LIST OF CONTRIBUTORS TO VOL. XXXIX.

Achorn, Dr. J. Warren, New York.
Allen, Dr. Charles W., New York.
Anderson, Dr. R. Harcourt, New York.
Ashmead, Dr. Albert S., New York.
Aulde, Dr. John, Philadelphia, Pa.
Austin, Dr. J. Edward, New York.

Babcock, Dr. J. L., Ithaca, N. Y.
Bailey, Dr. W. W., Fort Smith, Ark.
Baker, Dr. Charles H., Bay City, Mich.
Banister, Dr. J. M., U. S. Army.
Barry, Dr. John H., New York.
Beattie, Dr. Matthew, New York.
Blever, Dr. J. Mount, New York.
Bodenhamer, Dr. William, New York.
Bosworth, Dr. F. H., New York.
Briggs, Dr. Charles G., Gloversville, N. Y.
Brush, Dr. Arthur C., Brooklyn, N. Y.
Bryant, Dr. Joseph D., New York.
Bryce, Dr. P., Tuscaloosa, Ala.
Bulkley, Dr. L. Duncan, New York.
Bull, Dr. William T., New York.
Bunts, Dr. F. E., Cleveland, O.
Byers, Dr. J. Wellington, Charlotte, N. C.
Byford, Dr. Henry T., Chicago, Ill.

Camthey, Dr. Horace, Tarrytown, N. Y.
Chamberlain, Dr. F. T., Washington, D. C.
Cheesman, Dr. W. S., Auburn, N. Y.
Chichester, Dr. W. R., New York.
Churchill, Dr. Frank, New York.
Cleaves, Dr. Margaret A., New York.
Cleveland, Dr. Clement, New York.
Coe, Dr. H. C., New York.
Coit, Dr. Henry L., Newark, N. J.
Collins, Dr. Joseph, New York.
Cornell, Dr. Stanley S., Athens, Ontario, Canada.
Courtney, Dr. J. Elvin, Poughkeepsie, N. Y.
Crothers, Dr. T. D., Hartford, Conn.

Dana, Dr. Charles L., New York.
Davis, Dr. William B., Cincinnati, O.
Dawbarn, Dr. Robert H. M., New York.
Derby, Dr. Richard H., New York.

THE BRIGHT'S DISEASE OF PREGNANCY,

WITH ESPECIAL REFERENCE TO ITS MANAGEMENT.[1]

BY JAMES TYSON, M.D.,

PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA, PHYSICIAN TO THE HOSPITAL OF THE UNIVERSITY, ETC.

THERE is no subject of greater importance to the practising physician than the nephritis or Bright's disease of pregnancy. Its etiology differs somewhat according as it originates previous to pregnancy or during it, although the cause which makes a previous mild and comparatively harmless nephritis a serious one is the same as that which is responsible for the disease *de novo* during pregnancy. Such agency is the irritant effect upon the renal cells of some toxic substance in the blood, the precise nature of which is unknown, but which probably represents combined excrementitious substances from the mother and fœtus. This is, of course, always present in the blood of the pregnant woman, but it fails to produce its baneful effect on the kidneys of the majority of these for the same reason that the poison of scarlet fever circulating in the blood of its subject fails in the majority of instances to produce nephritis in it. It is, however, always sufficient to produce a serious aggravation of disease in kidneys already affected, as will be seen from what I have to say later.

That the toxic substance is contributed to by some product of the fœtus is shown by the fact that its consequences present themselves usually only in the latter half of pregnancy, when the size of the child is such that its excretions must add materially to those of the mother. That pressure of the gravid uterus upon the vessels of the kidney, as originally asserted by Lever in 1843, is of itself capable of producing nephritis, is claimed by few at the present day. Rosenstein alone, of the better-known authors, held this view in the second edition of his work published in 1870, but I do not know what his present belief is. It is not impossible that in the later stages of pregnancy, pressure may aggravate a nephritis otherwise caused, and of itself be capable of producing a slight degree of albuminuria without nephritis.

That the nephritis of pregnancy in the vast majority of cases is a parenchymatous or tubal nephritis, is *a priori* likely, for the same reason, again, that the nephritis of scarlet fever is a parenchymatous one—that is, that septic matters of this kind as a rule exert their influence upon the renal cells rather than interstitial substance. Accordingly autopsies discover a parenchymatous inflammation in the vast majority of cases, while they also exhibit differences of degree in this process, in fact, every grade between the simple congestion and cloudy swelling of the cells, and an advanced diffuse nephritis, in which the interstitial tissue is also involved. On the other hand, if the patient happens to have had an interstitial nephritis previous to pregnancy, this morbid condition will be found at an autopsy.

The symptoms, too, are the usual ones, and it is not necessary to dwell upon them. Œdema of the face, extending more or less thence over the body, albuminuria, tube-casts, derangements of vision, uræmia manifested in its various ways and especially by convulsions, are the chief, manifested in an order by no means constant. I desire simply to mention in passing, that while a decided majority of the cases of eclampsia in pregnancy are due to renal disease, this is not invariably the case, and there may be convulsions quite independent of such disease and of uræmia. This has been confirmed by autopsy. Albuminuria may even occur in consequence of the disturbances of circulation due to convulsions themselves, as has been amply shown in the case of epileptics, in whom, too, casts of the uriniferous tubules have been found. But that the cases of puerperal eclampsia independent of Bright's disease are exceptional I have taken some pains to show elsewhere.[1]

The diagnosis of the Bright's disease of pregnancy is so easy as to require no notice here, but I may say that it is still too common to allow pregnant women to go to term without examination of the urine.

The prognosis is, however, of such importance as to demand closer attention, especially in connection with treatment, and to this I desire to call attention as the most important part of my paper. In the first place, the acute nephritis of pregnancy is much more serious than acute nephritis from any other cause, while uræmia is the dangerous symptom which is responsible for the fact, so much so that if this danger be escaped the prognosis becomes quite favorable, even more so than in acute nephritis from other causes. Rosenstein has shown that convulsions occur in about one-fourth of all the cases, and that about thirty per cent. of the eclamptic cases die. This mortality, which certainly is not overstated, it seems to me can be diminished, and it was with this in mind that in June, 1889, I read a short paper on the induction of premature labor in the Bright's disease of pregnancy before the Section of Practice of Medicine of the American Medical Association at its meeting at Newport. Although but a year has elapsed since the publication of my paper, and although it has had the benefit of wide circulation of the Association journal, the subject seems to me of such importance that I venture to bring to your attention to-night the essential points of the paper. Scarcely a week passes in which some valuable life is not sacrificed to errors of practice under these circumstances, and this will continue to be the case until the profession is thoroughly aroused to a closer study of the complication in question. In the paper alluded to I called attention to certain conditions or combinations of conditions under which Bright's disease associated with pregnancy demanded that premature labor should be induced to save the life of the patient.

The first of these included cases of Bright's disease complicating pregnancy, in women in whom during a previous pregnancy there were certain grave accidents from the presence of which at one confinement may be predicted their certain recurrence in another. Such are structural changes in the brain as evidenced by paralysis of speech and paraplegia followed by slow return of motor power. Such lesions are sure to be followed by similar and worse ones, which almost invariably proceed to a fatal issue if allowed to go to term. In such, premature labor should be induced as soon as albuminuria appears. Such a case was related where I made the mistake of advising the husband to wait until more active symptoms

[1] Read before the Northern Medical Society of Philadelphia, November 28, 1890.

[1] The Causal Lesions of Puerperal Convulsions. A paper read before the Pathological Society of Philadelphia, April 28, 1878, and published in its Transactions.

presented themselves before interfering and inducing premature labor. The more active symptom was so speedily followed by death that there was no chance to interfere.

The second category included all primipara in whom Bright's disease existed before marriage. These cases in my experience are invariably fatal if allowed to go to term, and I strongly disadvise marriage when I am aware of the presence of Bright's disease, however well the patient may seem. Such advice is not, however, always followed, and in many more instances the patient and physician are alike ignorant of the previous presence of the disease. It is, of course, a proposition difficult to sustain, but I am inclined to believe that many more cases of fatal puerperal eclampsia in primipara than suspected have been women who have had Bright's disease before marriage, and ridiculous as it may seem, at first thought, I have no doubt that if the urine of every girl were examined before marriage some lives would be saved; first by persuading her on discovering the disease to give up the idea of marriage, and second by providing a treatment in the event of pregnancy occurring. In these cases premature labor should be brought on as soon as conclusive symptoms, such as increased albuminuria, tube casts, decided dropsy, or severe headache make their appearance. Some delay may be permitted if the viable age be not too distant, but any attempt to carry such cases to term has in my experience had but one issue, and that a fatal one.

Third, I think premature labor *may*, with propriety, be induced—and note I do not say should unvariably be induced—in pregnancy complicated by Bright's disease where signs of a renal affection complicating a previous labor persist after such labor, even though the patient passed safely through the ordeal of labor. Here, too, pregnancy should be avoided, but it is often next to impossible to prevent its occurrence.

The question as to when labor should be brought on is not so easily answered. For it is not impossible for such a case to go to term and even to be delivered without accident, while the explanation is not difficult. There can be no doubt that the long-continued presence of a Bright's disease, if it remains at a stand-still or increases but slowly, results in a degree of accommodation of the organism to its presence. This is brought about by an increased action of organs which are complemental to the kidneys, namely the skin, lungs, and bowels. This existing, the additional work thrown upon the kidneys during pregnancy is supplemented in larger proportions by these organs and the danger is lessened; while immunity is still further favored by the greater ease of the multiparous labor. Hence, as stated, no definite rule can be laid down, but such cases demand the closest attention and utmost vigilance of the practitioner, and should large albuminuria and dropsy associated with intense headache and scanty secretion of urine be present, or the slightest sign of uræmia make its appearance, labor should be brought on regardless of the viability of the child. More frequently, perhaps, viability may be awaited with safety. A saving clause in the history of these cases is that they are very apt to miscarry, and thus save their own lives, and in the paper alluded to I gave the history of two women in whom labor was thus spontaneously terminated and risk to life averted. One of these patients has since died of the further development of her disease without having again become pregnant.

Finally, there remains a set of primipara in whom Bright's disease, if it makes its appearance during pregnancy, is almost sure to be fatal, and this includes women married late in life. The first question which suggests itself is, of course, what age would be named as marking such a period? Nor is it easy to answer in absolute terms, but this much may be said: If a woman who attains the age of forty before marriage, becomes pregnant, and acquires Bright's disease she is almost certain to perish in her confinement, while the danger is scarcely less two years younger; and when it is remembered that in all primipara Bright's disease, whether acquired before or after pregnancy, is an extremely dangerous complication, it is but reasonable that women at thirty-five under these conditions should be watched with the extremest solicitude.

It may be said that my catagories include practically almost all cases of Bright's disease in pregnancy. This is sufficiently near the truth to make it worth while to formulate a statement covering cases in which pregnancy may be complicated with Bright's disease and which go to term without accident. Such are the pregnancies of multipara who have not had Bright's disease in previous pregnancies. These are not infrequent and doubtless many here present will recall cases of this kind which they have carried to a favorable issue. It is these cases which are apt to be remembered and quoted in justification of non-interference in the Bright's disease of pregnancy, but it will be noted that none of them fulfil the conditions I have named. It is not altogether easy to explain in every case why thus immunity should occur. Some doubtless are saved by the ease and celerity with which multiparous confinements are often accomplished. For there is no doubt but that the straining and other phenomena incident to prolonged labors tend to produce an accumulation of whatever it is which often explodes in a convulsion and its sequelæ, even, as already stated, independent of Bright's disease; but what it is that saves these women from serious symptoms almost up to the hour of confinement while in the other cases the dangers assert themselves so much earlier, is not so easy of explanation. In the matter of multipara as compared with primipara it may be that through previous pregnancies the economy acquires a facility of excretion through organs complemental to the kidney, but so far as I know no proof of this exists. The fact remains, however, a significant one. And why pregnancy succeeding Bright's disease should be so much more dangerous than a Bright's disease supervening on pregnancy, in other words why damaged kidneys plus pregnancy should be worse than pregnancy plus damaged kidneys, as seems to be the case, I am unable to explain.

It remains to point out briefly the treatment which should be adopted in cases where it is concluded to attempt to prolong gestation to the viable period or the end of pregnancy. To keep up elimination and thus to prevent the over-accumulation of toxic substances in the blood is, of course, the first indication. And while the kidneys present themselves as the natural channel through which this is to be accomplished they are seldom sufficient, and the bowels become the next, and indeed often the first and most convenient medium. Especially should constipation be avoided, while a brisk purge has often averted a uræmic attack. Continued looseness of the bowels is a safety valve which in these cases can scarcely be abused. The skin is also a serviceable medium for elimination, and is continuously availed of by warm woollen clothing next the skin, the effect of which is increased by the uniform temperature of the bed. Daily warm or hot baths, according as to which may be found more efficient, increase this effect, while the simple spirit of nitrous ether in full doses is a double agent acting upon the kidneys as well as most efficiently favoring the action of the skin. Jaborandi or its active principle pilocarpin in small doses, just enough to keep up a gentle but constant action of the skin, is also valuable. The hot-air bath or vapor bath may also be used with excellent effect. These are cases, too, in which a diet of pure milk or milk diluted with water or carbonic-acid water diminishes the dangers with which the patient is threatened.

When uræmia actually sets in any or all these agencies, except possibly jaborandi, may be employed in increased doses if available, but whatever may be the hesitation of inducing premature labor previous to its appearance there should be none after it; and I can emphasize the conclusion of my paper with no more truthful or appropriate words than those of Bartels,[1] who says, "the treat-

[1] In Ziemssen's Cyclopædia of Practical Medicine, English translation, vol. xv.

ment of eclampsia during labor should be guided by the experience which has taught us that the dangerous accidents cease entirely in nearly one-third of all the cases as soon as the uterus is emptied." While this is being carried out the dangers of the convulsion may be diminished by blood letting, by chloroform, and by chloral. Blood-letting is needed almost without exception in every case of uræmic puerperal convulsions, and many a case is lost through its omission. As soon as it has been carried out as far as seems safe or judicious chloroform or chloral should be called into play to control the convulsion; or one or the other may be used simultaneously with the bleeding. Under no circumstances is the action of chloral more happy, and the rectum affords a medium of administration as prompt and efficient in its operation as the mouth, which is generally unavailable for the purpose. No less than a drachm in solution should be given at such a time by enema, and it is unwise to temporize with smaller doses.

THE REALITY OF RABIES.[1]

By CHARLES L. DANA, M.D.,

PROFESSOR OF NERVOUS AND MENTAL DISEASES, NEW YORK POST-GRADUATE MEDICAL SCHOOL, NEW YORK.

MR. PRESIDENT: I cannot speak upon the subject of rabies from the stand-point of an experimentalist, and my only apology for accepting the invitation to join in the discussion to-night is that I have been an interested student of the question for a number of years. During the past summer I have visited the Pasteur Institute in Paris, where Messrs. Pasteur and Grancher courteously gave me opportunities of observing the work going on, and of learning their present views upon the subject of the pathology and prophylaxis of rabies. Through the kindness of Mr. Horsley, of London, also, I was furnished with some interesting original documents, as well as a series of photographic studies illustrating the classical and pathological aspects of the disease. M. Paul Gibier, of this city, has also kindly shown me the workings of his laboratory, which, I am bound to say, compare favorably with those of the Paris Institute.

There is still a great deal of scepticism in regard to rabies, its nature, its frequency, and even its existence. There is also a great deal of scepticism and even hostility felt toward the work of Pasteur upon this subject.

In view of this fact it seemed to me that I could not better employ my time in this discussion than in attempting to show what has, in my opinion, been settled in regard to these points.

I shall, therefore, take up the question of the reality and specific character of rabies in lower animals and in man. This will naturally involve a consideration of the pathological aspects of the disease, and to some extent the principles upon which prophylactic inoculations are based.

The Tests of the Specific and Distinct Character of a Disease.—In order to prove that a certain disease is autonomous, distinct, and special we must establish the fact that its etiology and its clinical history are essentially uniform, or that the anatomical changes found after death are the same, or that inoculations of animals with the secretions or tissues of the victim of the disease reproduce the disease. The proof of the unity of a disease is therefore etiological, clinical, anatomical, and experimental. The unity of some diseases can be established by only one or two of these methods, not by all. In the case of rabies, a comparatively rare and obscure disorder and occurring in lower animals, so that only objective symptoms can be studied, it is imperative that all the proofs should be brought into use, and fortunately this can be done.

I. **The Etiological and Clinical Proof** of the existence of the disease rabies is based upon the fact that different observers in every part of the world, from the time of Cornelius Celsus, Galen, and Aurelian to that of John Hunter (1793), Youatt (1830), and Hertwig (1829), and many distinguished living writers have all united in describing a disease in the dog having essentially the same origin, symptoms, course, and termination. It is not my purpose to enumerate these distinguishing characters. It is sufficient to say that in them should be included the mode of infection, the period of incubation, the mental excitement, the tendency to bite, the emaciation, acute course, the convulsive and paralytic phenomena, and the invariably fatal termination. But the clinical proof of the existence of rabies is not alone sufficient either to establish it as a specific disease or to make a diagnosis of it in a particular instance. It has long been known that symptoms resembling rabies may be caused by enteritis, worms, metallic poisons, by farcy, and organic diseases of the central nervous system.

It is true the symptoms when taken in their entirety are generally sufficient for diagnosis. Among 207 dogs pronounced rabid or probably rabid in Würtemberg in 1865–1866, 108, or about fifty per cent., were found to be really so. And Bollinger [1] estimates this as representing about the accuracy of a professional diagnosis, it being remembered that physicians and veterinarians are always anxious to be upon the safe side.

It follows from the foregoing that those who state that alleged cases of rabies in dogs may be cases of some other disease are stating what no one has ever denied.

Having carefully read the account of Spitzka's experiments [2] as to this point it appears to me that he simply showed that symptoms resembling rabies may be caused by meningitis or cerebritis, which no one has denied. Apart from this the experiments have no bearing on the question of rabies at all, and they certainly do not weaken the value of careful experimental tests for rabies made either upon rabbits or dogs.

II. The Anatomical Proof of the Specific Character of Rabies. Pathological Anatomy of Rabies.—It is not believed by M. Pasteur and his associates that there are any definite characteristic lesions of rabies.

If any were present they would be found chiefly in the medulla and spinal cord.

As a matter of fact there are found here very uniformly minute changes which consist of accumulations of round cells in the perivascular spaces, forming what has been termed a miliary abscess. These so-called miliary abscesses are most numerous in the later stages of the disease. They may not be found at all in the early stage; and since, in the case of man, the disease usually kills very soon, fewer changes are found in the human nerve-centres. In paralytic rabies in man, however, these changes are more decided and widely diffused.[3] They are always most marked in the medulla, next in the spinal cord, and last in the brain. If patients with rabies lived long enough we could say, therefore, that anatomically rabies is multiple focal bulbar myelitis. Miliary abscesses, however, are not characteristic of rabies alone, but are found in other diseases, especially infective fevers and meningitis.

A number of other changes, such as softenings, congestions, minute hemorrhages, etc., have been described as occurring in rabies. Golgi has described peculiar changes in the nuclei of the nerve-cells of the medulla. A microbe which can neither be colored nor cultivated can be seen in the brain tissue in rat rabies,[4] and Babes has described a microbe which Gibier states is identical with the one he has figured. The proof of its specific character is yet wanting. No one has certainly found a microbe, although rabies is probably a microbic disease. And the symptoms of rabies are caused not by any organic change in the nervous tissues, but by a profoundly irritant poison, the product of the microbe's activity.

is, therefore, mainly a negative one. By it we can exclude meningitis, encephalitis, hemorrhages, injuries, etc. There are incidental anatomical changes which help in forming a particular diagnosis, but are not essential parts of the disease. Such are the presence of abnormal substances in the stomach, hyperæmia, and hemorrhagic extravasations in the stomach, congestion of the larynx, fauces, etc.[1]

III. The Experimental Proof. — This may be put briefly in this way:

1. The virulence of the poison of rabies was found by Pasteur (as it had been by others) to be chiefly in the medulla, cord, and brain.

2. Animals are made rabid generally by subcutaneous inoculation of this virulent nervous tissue; but they are practically always made rabid by subdural inoculations after trephining.

3. Rabbits inoculated in this way develop a paralytic form of rabies which has a very definite incubation, fifteen to twenty-one days, very characteristic symptoms, course, and termination.

4. This disease in rabbits, called paralytic rabies, is true rabies, because dogs inoculated with its virus develop after a normal incubation true rabies.

Thus by establishing the existence and symptomatology of rabbit rabies, and by furnishing a means of always and easily producing it, Pasteur has given us an experimental test of the disease which can be applied with comparative ease. Pasteur experimented still further with the virus of rabbit rabies and reduced it to the most definite conditions. He found that by continued successive serial inoculations of the rabbit the period of incubation after a time was reduced invariably to six or seven days, the rabbits dying on the ninth to eleventh day. He thus fixed the intensity of the virus and the symptomatology of the disease absolutely.

In the Pasteur Institute are ten different cages, each containing an inoculated rabbit. The rabbit in the tenth cage is just dying. That in the first has just been inoculated. Between them one sees rabbits in each stage of paralytic rabies. There is a mathematical precision about the development and course of the disease which affects one with admiration and arouses afresh a confidence that there are laws and certainties in medical science.

In the light of all the evidence thus presented, it seems to me that no one can any longer deny the specific inoculable character of rabies. Further discussion with those who deny it will serve no good purpose. It is, indeed, only in regard to the significance and value of Pasteur's experimental tests that doubts and criticisms still are circulated. Those who distrust Pasteur, however, will find that his work has been abundantly confirmed elsewhere.[2]

Professor A. Högges, of Budapest, has recently published a monograph ("Die Experimentale Basis der Antirabischen Schutzenfungen Pasteur's," Stuttgart, 1889) which includes experimental work patiently carried on for four years and which entirely confirms the value of this inoculation test of rabies. Dr. Dowdesdell,[3] and Mr. Victor Horsley have repeated and verified the tests. So also have, in Italy, Di Vertia and Zagari,[4] and, in this country, Ernst,[5] Shakespeare, and Biggs. There is now, so far as I can learn, universal acceptance of this experimental test by all pathologists who have carefully employed it, or examined the work upon which it is based.

Does the Specific Disease Rabies Occur in Man? — I have spent a good deal of time upon this point, because its establishment is the key to the whole question of the reality of rabies in man, and to all the practical points regarding its prevention. It is unnecessary now to

[1] The engorgement of the stomach of a dog with foreign indigestible substances is considered in connection with other symptoms almost pathognomonic of rabies (Law). It is certainly very rare to find such substances in the healthy dog's stomach. In some experiments made by myself (American Journal of Medical Sciences, 1882) on the action of pepsin I examined the stomach contents of nearly forty dogs and never found foreign matter in them.

go over at any length the second question as to the occurrence of genuine rabies (hydrophobia) in man. I do not know that such occurrence is seriously doubted by scientific men anywhere. Yet I am justified in taking up the point, since doubts and denials are expressed not only in certain prominent medical journals but in discussions on the subject in the lay press. Wide circulation, especially, has been given to the statement that rabies in men is not a specific inoculable disease,[1] but a more or less incidental result of bite and fright, of trauma, hysteria, tetanus, meningitis, or insanity.

The proof that a specific inoculable disease known as rabies or hydrophobia affects man is furnished us by the four criteria I have already given, viz. : (1) the etiological; (2) the clinical; (3) the anatomical; (4) the experimental. This last is again conclusive and puts the fact as much beyond questioning as any point in medical science can be placed. The medulla and cord of men who have died from rabies due to the bite of a dog have been inoculated subdurally in rabbits, and paralytic rabies is produced with only a difference in the period of inoculation. The course and termination are identical with that caused by inoculating rabbits with the virus from a rabid dog. These experiments have been done by different observers in different parts of the world. The accounts of them can be read in the communications made by Pasteur and others in the "Annals de l'Institut Pasteur," in the report of the British Parliament Committee in 1877, and in the "Transactions of the London Clinical Society, November. 1888," and in numerous other papers.

Many doubt the existence of human rabies because they have never in a long experience seen a case. Rabies in man is undoubtedly a rare disease in this part of the country, but cases are constantly occurring here and there. Within six months two cases were brought to Bellevue Hospital. The frequency of the disease in general is not to be estimated by its occurrence in America. Its prevalence in Europe is very considerable, as has been shown by the records collected by Bollinger before Pasteurism began, and by later writers.

Pasteur's work has called attention also to the fact that a paralytic form of rabies sometimes affects man, producing symptoms resembling acute ascending paralysis, or Landry's paralysis. It is not impossible that cases of this disease have been in reality of rabietic origin. In questioning the many general practitioners from various parts of the country with whom I come in contact, I have found that many could recall cases of mysterious acute, progressive, fatal paralyses, whose nature and cause have completely puzzled them. It may be that the paralytic rabies in man is, therefore, not such an extreme rarity. Gamaleia,[2] Ygouff,[3] Ufridizzi, Bristowe and Horsley,[4] and Surgeon-Major Keegan have all reported cases of paralytic rabies in man.

In the attempt to discredit Pasteur and disprove the existence of human rabies a great deal has been made of pseudo-hydrophobia, or lyssaphobia, and of its alarming frequency and extraordinary dangers. All the old-wives' tales illustrating the power of the imagination to disorder and annihilate the body have been rhetorically rehearsed, and a fear of hydrophobia has been supplanted by a fear of the fear of hydrophobia, so that good people are shivering in terror over an innocuous shadow while they smile incredulously at the fatal substance.

As a matter of fact there are no authentic clinical records of a single case in which fear of hydrophobia has caused a disease measurably similar to rabies, by which I mean a disease not easily distinguished from rabies by an intelligent physician.[5] Nor is there, so far as I can find, a single authenticated case of death from this particularly hypothetical phantasm.[6]

The imagination alone cannot fatally inhibit the vital functions; the *psyche* cannot suddenly destroy itself by creations of the imagination, any more than the *soma* can without help commit *auto da fé*.

The legend of the man who died because he was told that he was being bled to death, while in fact a stream of warm water was allowed to trickle along his arm, ought to be laid away with the ancient and inane myths. It is not historically authenticated and it is psychologically impossible. Bear in mind that I am speaking of the effect of imagination upon healthy bodies. No doubt fright can kill a person who is already toppling on the verge of the grave, or who has a weak heart, or but one lung, or who is ripe for an insanity. But as for hydrophobic fright inducing an acute and fatal disease in strong men or healthy women, it is inconceivable.[1]

Prophylaxis.—Closely connected with the subject of the specific character of rabies in man and the lower animals, comes the question of the production of immunity from its horrible and fatal effects. I shall leave any elaborate argument on this question to others, but I cannot forbear bringing up some points, since they are so intimately woven in with the line of argument I am trying to pursue. The establishment of the specific inoculable character of a disease gives a presumption in favor of the power of securing immunity from it, for in the great majority of specific diseases the animal body either naturally possesses or may acquire immunity. This is true of all or nearly all the non-suppurative infections, from syphilis to small-pox. As regards animals, it seems to me that no one who carefully reads the evidence given in Pasteur's communications can deny that by his method he succeeds in rendering dogs refractory to the bite of other rabid dogs, also to subcutaneous and even to subdural inoculations of the virus of street rabies and of the "fixed virus;" also that even after subcutaneous inoculations of this virus or after infecting bites, he can prevent the development of the disease. His experiments have been reported in detail, and have been followed by such experienced laboratory workers as Lauder Brunton, Mr. Horsley, and Dr. Burdon Sanderson.

Besides these they have been repeated and confirmed by Ernst, Babes, Högyes, Bujwid, Di Vestia and others.

Much has been made of the experiments of Von Frisch, of Vienna, who alone, so far as I know, failed to get the same results as Pasteur. But his failure is easily explained. The rabbits used by him were smaller and the cords lost their infective properties too soon, while he himself failed to operate aseptically. Instead of continuing his experiments with the desire to eliminate these sources of error, Frisch stopped his work and announced, much to the satisfaction apparently of the Viennese world, that the method was a failure. And Billroth said, "French science is advancing with a club foot," and only two papers out of nearly a hundred were read by Frenchmen in the Section of Internal Medicine at the Berlin International Congress.

Now Professor Högyes had at first the same experience as Frisch, but he continued his work and finally succeeded in making the dogs refractory to rabies.

It may be admitted that the process is not always cer-

[4] Transactions of the London Chirurgical Society, 1888.
[5] Dr. Ernst's case of spurious rabies, cited at the discussion of his subject, exactly proves this point.
[6] Romberg cites a fatal case of lyssaphobia from Trollert, but there is no evidence that the trouble was not either true rabies or acute alcoholism, since the symptoms developed directly after a spree and three and a half months after a bite. Another very ancient and doubtful case of fatal lyssaphobia is reported in the memoirs of the Royal Society, of Montpellier. It is curious that modern literature furnishes no fatal cases; and that those who speak so fluently of it have never reported a case.

[1] There have been perhaps fatal cases of tetanus following bites of dogs, and there have possibly been fatal cases of acute mania generated in the predisposed by the fright. These extremely rare and doubtful instances will explain the fatal cases of so-called pseudo-hydrophobia.

It is but just to say that in the discussion on this question the distinguished chairman asserted that as one result of the discussion it had been proved that there was such a thing as false hydrophobia and that this disease had been fatal.

I did not deny that false hydrophobia occurred, but only that it was not like true hydrophobia, and was easily distinguished from it. No one reported an authentic case of fatal lyssaphobia.

tain or absolutely perfect. Of this others can speak with much more authority than myself; but the essential principle has been established as immutably as anything in biological science.

Thus it seems to me, in conclusion, that the following points are established with regard to rabies :

1. Rabies is a specific inoculable disease. It occurs not only in lower animals but in man ; and the etiological, clinical, anatomical, and experimental tests all unite in proving that rabies is the same specific disease in whatever animal it occurs.

2. The experimental test of the disease by subdural inoculation of rabbits with nervous tissue is a certain method (barring the natural accidents of surgical experimentation) of determining the existence of rabies in a given case.

3. The most constant anatomical change in rabies is a multiple focal bulbo-myelitis. This condition is found in man if life is prolonged.

4. The paralytic form of rabies may occur in man, assuming somewhat the type of Landry's paralysis.

5. The virus of rabies resides chiefly in the nervous centres and can be rendered definite in action by carrying it through rabbits.

6. Dogs and other animals can be rendered refractory to rabies by protective inoculations.

7. Spurious hydrophobia is rare, non-fatal, and easily distinguished from true rabies.

HYDROPHOBIA—ITS CLINICAL ASPECT.

By LANDON CARTER GRAY, M.D.,

PROFESSOR OF NERVOUS AND MENTAL DISEASE OF THE NEW YORK POLYCLINIC.

When it became my official duty, as Chairman of this Neurological Section, to provide some subject of general interest for one of the general meetings of the Academy, I could think of no available one more opportune than hydrophobia, as the startling claims of Pasteur, and the multiplication of his so-called institutes throughout the world, have awakened fresh interest in a disease that has excited the curiosity and the fear of mankind from time immemorial. Moreover, the sensationalism of the newspapers about every fresh bite of an animal, and the uncertainty of physicians who have seen only one case or none at all, would be additional reasons for a discussion of this kind.

At the very threshold of the subject we are confronted by the question as to whether there is such a thing as rabies,[1] or hydrophobia. There has been much and bitter discussion upon this point during the last few years. Those who would answer this question in the affirmative allege as proof the fixed belief of ages, and the many epizoöties of which we have historical record. The very earliest writers speak of rabid dogs, and they were known as far back as the days of the Asclepiadæ, the descendants of the God of Medicine, Æsculapius ; while there are very few parts of the world, whether in the tropics or the arctics, in which an outbreak of it has not been described at some time or other. At times it has raged with great fury, as in Northern Germany from 1851 to 1856, when at Hamburg alone 600 cases were observed among dogs, 267 occurring in the year 1851. In England, in 1856, it raged severely among dogs, and in a herd of deer, destroying nearly one hundred of the latter. In Wurtemberg, according to the veterinary professor Hering, from January 1, 1840, until the end of February, 1842, it affected two hundred and thirty dogs and twenty-one bitches. In 1866 there were thirty-six deaths from hydrophobia reported by the Registrar-General of Great Britain. It has never been very prevalent in this country, although local epizoöties of it have been reported from time to time. It is stated that it is now raging in a herd of deer belonging to the Marquis of Ipswich.

In almost all of these epizoöties human beings have been bitten by the rabid animal and have died, although it has never been spread from one human being to another as it has done in animals. It would seem, therefore, to be conclusively proven that there is a disease which can rapidly exterminate a kennel of dogs, a flock of sheep, a drove of hogs, or a herd of deer, and which can render the timid skunk, badger, and fox ferocious and dangerous, and make of the wolf a beast of prey as fierce as a royal Bengal tiger. It would also appear to be conclusively proven that many people have died after being bitten by these rabid animals. But there has sprung up in this country, in the last few years, a small number of very decided opponents of these claims, such as Spitzka, Brill, Dulles, Stockwell, and others; and, unless I am very much mistaken, they have voiced to some extent the feeling of scepticism that prevails among American physicians. In the first place, they say, many mistakes are made in diagnosis, so that animals are said to have rabies when in reality they have some one of many disorders that may cause similar symptoms, such as epilepsy, angina or sore throat, gastritis and enteritis, distemper, foreign bodies in the mouth and throat, tetanus, worms in the frontal sinuses or in the small intestines, and ulceration of the internal ear. In certain countries, extending from the sources of the Vistula to the Carpathian Mountains, there is endemic a disease known as the "Plica Polonica," attacking mankind, horses, cows, sheep, wolves, foxes, and dogs, in the latter closely resembling rabies, although the bite of these animals is not followed by hydrophobia. Spitzka has introduced into the skull cavities of dogs such non-rabic material as the spinal cord of a healthy calf, common yellow soap, and stale horse's urine, producing a purulent meningitis and meningo-encephalitis, and the symptoms of dumb rabies. Miller has reported three cases of seeming rabies in the cow, in which clusters of the parasite known as strongylus tetracanthus were found in the intestines. It is not unreasonable to suppose that the bite of an excited animal may be very dangerous, as it is an elementary fact in physiology that the secretions of the human female breast are at times fatal to the child. My friend, Dr. E. F. Brush, informs me that one of the earlier Borgias obtained a subtle and most dangerous poison by dipping a ring in the saliva of a hog which had been hung up and kept excited to a blind fury for a long time. The variations are almost incredible that are alleged to exist in the period of incubation of hydrophobia. Fleming states that the average in England has been from thirty to fifty-nine days. According to Tardieu, it may vary from one month to twelve. Trousseau says that it may run from a few days to a year. In Algiers it varies from twenty to two hundred days. Sauvage speaks of a peasant who was suffering from the most pronounced hydrophobic symptoms on the third day after being bitten by a mad wolf. Chirac tells of a merchant who was bitten by a mad dog at Montpellier, afterward resided ten years in Holland, and was suddenly attacked by hydrophobia on his return to France and learning of the death of a brother cadet who had been bitten by the same animal. Finco, of Padua, narrates the case of a young woman who became hydrophobic fourteen years after receiving a wound from a rabid dog. Even Gowers states that the period of incubation is longer and more variable than that of any other known acute specific disease, and

[1] There should be considered briefly some details of nomenclature about which much confusion prevails. By usage the term rabies is given to the disease in the animal, while the malady in man is termed hydrophobia. This was so stated in Fleming's book in 1872, and has since been adopted by the standard dictionaries and writers. I see no reason, however, why it should not be called rabies in the human subject. The disease was termed lyssa by the Greeks, meaning a worm, a term given to the frænum of the dog's tongue, which was supposed in the early days to be a worm, and was extirpated as such. This superstition lingered even as long as the early part of this century, when a Russian physician, by the name of Marochetti, claimed that in all cases of hydrophobia pustules appear under the tongue at a certain time of the incubation of the disease. The German writers still retain this name of lyssa. The spread of an infectious disease among animals is called an epizoöty (from ἐπί, upon, and ζῷον, an animal) ; just as the spread of an infectious disease in the human being is called an epidemic (from ἐπί, upon, and δῆμος, the people).

believes that many well-authenticated cases have occurred eighteen months after the wound. This extreme variableness in the period of incubation lends credence to the belief, firmly held by many competent observers, that death from fear can occur with symptoms closely resembling the true disease. These are the cases of so-called lyssaphobia or hydrophobia.

Although a recent writer has characterized such a belief as childish, it is yet a matter of clinical observation that great psychical shock can produce mental disease and death.

I have a patient in whom an attack of melancholia of eighteen months' duration was caused by her lover being suddenly thrown from his horse and killed before her eyes. I know of another case in which a woman's husband, who had been supposed lost at sea, suddenly appeared before her, when she became speechless, mumbling, and, preserving only consciousness enough to gently caress his face for a few hours, sank into a coma and died. A patient of mine with transverse myelitis, who had improved greatly, was much frightened by his room catching fire, and in a few hours he became delirious, and within twenty four hours he was dead.

I have under my care at the present moment a stalwart, resolute young man, to whom the Secretary of the Treasury has just presented one of those rare medals of gold that are only given to those who save a life at imminent danger to their own; and this man, notwithstanding he had nerve enough to plunge into the raging surf to rescue a fellow-being, has not been able to do a day's work since, suffering from those well-known symptoms which Oppenheim describes as traumatic neurosis, and which occur so frequently after railroad accidents. If these instances be not sufficient, a perusal of Tuke's book on the influence of mind on the body ought certainly to convince any impartial mind that such an overwhelming fear as is that of hydrophobia is quite sufficient to induce death, the more especially as a number of suicides have been committed from this very dread. Very few men in this city of New York, or, indeed, in this country, have seen a case of hydrophobia. Indeed, one of the great difficulties that I have encountered in arranging this debate has been that there is not a neurologist in New York City who has seen more than one case in his own practice, although some few have seen two or three cases at the great hospitals, while many men of great experience have seen none at all.

For my part, in an experience of twenty years as student and practitioner, I have never seen but one case, and, to be guilty of an Hibernianism, I would not swear to that. In this city of New York, from 1855 up to the present time, the number of deaths from hydrophobia have been as follows, according to the figures very kindly furnished to me by Dr. John T. Nagle, viz.: 1855, 4; 1856, 3; 1857, 2; 1858, 0; 1859, 2; 1860, 0; 1861, 5; 1862, 1; 1863, 3; 1864, 1; 1865, 3; 1866, 2; 1867, 4; 1868, 1; 1869, 5; 1870, 3; 1871, 7; 1872, 6; 1873, 0; 1874, 5; 1875, 0; 1876, 5; 1877, 4; 1878, 2; 1879, 0; 1880, 0; 1881, 3; 1882, 1; 1883, 1; 1884, 1; 1885, 0; 1886, 0; 1887, 1; 1888, 0; 1889, 1.

Thus, in a period of time covered by thirty five years, there have been seventy-six deaths, in nine of these years there have been no deaths, and it has twice happened that for two years at a time there was not a death. One of the deaths in 1874 is that of a man who was bitten by a dog supposed to be rabid, and a coroner's inquest was held, the cause of death being stated to have been lyssaphobia. I come in contact with many physicians from different parts of this country, and it is very exceptional to have one tell me that he has ever seen a case of hydrophobia.

From this necessarily cursory review of the *pro* and *con* of the subject, we may draw the conclusion, I think, that frequent mistakes are made in the diagnosis of rabies and hydrophobia; that death can be caused by the fear of the disease; that the symptoms of the so-called dumb rabies may be caused by simple purulent meningitis and meningo-encephalitis; and that very few cases of either rabies or hydrophobia have been observed in New York City or in the country at large. Admitting all this, however, the question still remains as to whether there is a true rabies or a true hydrophobia. For my part, I believe that there is a disease running a fatal epizoötic course in the dog and other lower animals, and capable of being communicated to the human being and causing death, although the evidence of this will rest mainly upon the pathological and experimental considerations which will be presented to you by Dr. Dana, Dr. Biggs, and others. Whether you call this rabies or something else is a matter of entirely secondary consideration.

If we may trust the present writers upon the subject, the symptoms of furious rabies in the dog are as follows: Alteration in the animal's demeanor, so that it becomes sullen, shy, and restless; hallucinations of sight, so that imaginary objects will be bitten or snapped at; strange and erratic movements, indicative of mental aberration; transition from obedience and affection to semi delirious outbursts, or to frenzy and fury; irresistible tendency to roam, so that great distances may be covered in a surprisingly short time; great tendency to bite; greatly increased salivary secretion, which becomes thicker and more viscid; a peculiar howl, which is described by Fleming as being neither a bark, howl, growl, nor snarl, but a curious jumble of all—the howl being predominant; finally exhaustion, paralysis, and death. In dumb rabies there is the characteristic paralysis of the lower jaw, so that the dog is incapable of either eating or drinking, or of closing the mouth; sometimes also a certain amount of tumefaction of the pharynx and tongue, and finally paralysis of the extremities and death. In so-called tranquil rabies the animal is in a condition of coma. None of these animals show any aversion to water, contrary to the popular belief.

The symptoms in the human being consist at first of general malaise, mental depression, slight insomnia, and some vague distress about the throat. Attempts at drinking occasion pharyngeal spasm, which spreads to the muscles of respiration, causing a short, quick inspiration like that of a sudden effusion of cold water, this increasing in severity to a strong inspiratory effort, in which the extraordinary muscles of respiration take part, so that the shoulders are raised, and even the facial muscles may draw the angles of the mouth outward. Reflex excitability is enormously increased, the slightest cutaneous impression bringing on a spasm. Salivary secretion is much increased. Vomiting is common. The muscular spasm, confined at first to the muscles of deglutition and respiration, may spread to the other muscles of the body, and the convulsions may become general, causing continuous general muscular rigidity, or opisthotonos, or they may be co-ordinated and closely resemble the hysteroid variety. Delusions may occur, or even wild delirium. The differential diagnosis in the human being is from tetanus, especially when it is endemic, as on Long Island, from that form of organic brain disease known as delirium grave, from acute mania, from tetanilla, from epilepsy, from hysteria. There is no such dread of water as to warrant the term hydrophobia, as many of even the recent writers would have us suppose; but the spasm of the muscles of deglutition at the sight of water is only a part of the general reflex excitability, as is shown by the fact that glittering objects, loud noises, draughts of air, may cause the same spasm, or kindred ones, in other muscles. In many cases there is a curious alternation of consciousness with furious action. Thus, a patient begs the bystanders to go away, as he fears he may do them damage; or, as Dr. Ernst tells me that a patient of his did, a man may fly at the throat of an attendant, saying, "I can't help it!" The temperature ranges from 100° to 104° F., or, exceptionally, 106° F. Remissions are frequent. Death is sudden or by gradual coma. Paralysis does not generally

occur, although it has been stated that paralytic symptoms similar to those of acute ascending or Landry's paralysis may occur; but as there is only one case to support this claim, and as this one—a man named Goffi—had been inoculated by Pasteur's intensive method, and died notwithstanding, it needs no eminent logician to perceive that the probability of the symptoms having been caused by Pasteur's intensive inoculation is much greater than the probability of their having been caused by rabies.

HYPNAL, THE NEW NERVINE.[1]

By J. B. MATTISON, M.D.,

BROOKLYN, N. Y.

MEMBER OF THE AMERICAN ASSOCIATION FOR THE CURE OF INEBRIATES; OF THE NEW YORK NEUROLOGICAL SOCIETY; OF THE MEDICAL SOCIETY OF THE COUNTY OF KINGS.

I HAVE the pleasure of offering you to-night a therapeutic novelty—the only supply in America, so far as I know, of hypnal, specially imported for me—and giving you an account of my trials with it, which is, so far as I am aware, the first presented in this country.

Tersely told, hypnal is the product of combining equal parts of hydrate of chloral and antipyrine. It is an oily liquid of ether odor and chloral taste. Brought out last year in France, by Blainville, it was noted later by Behal and Choay, who found three distinct compounds, one of which was worthless; the others were called monochloral antipyrine and bichloral antipyrine. Reuter, testing one, gave it the dreadful name of mono-tri-chloral-acetyl-dimethyl phenyl-parazolone, and declared it inert. He, however, used the non-active product. Dr. Bardet, of the Cochin Hospital, made the first medical experiments, and—Heaven bless him!—called it hypnal. He reported twenty-two cases in which one-gramme (fifteen-grain) doses acted well as a sedative, soporific, and anodyne, and especially useful in insomnia due to cough or pain.

Frankel—whose paper in the September number of the *Bulletin gén. de Thérapeutique* is the latest from foreign sources — after thirty-three trials, wrote in its favor. Schmidt commends it; so, too, Quintard.

The consensus of opinion among continental observers is that hypnal is an efficient sedative, soporific, and analgesic; it is more hypnotic and less depressing than chloral; it is not caustic like chloral nor irritant like antipyrine, and it is more readily taken, being more tasteless than either.

On respiration it is much like chloral; on circulation it is less disturbing than chloral. It is antipyretic, and non-irritant by mouth, bowel, or skin. It is said to be particularly adapted to children, and to patients with phthisis, lessening fever, pain, insomnia, and unrest. Schmidt found that fifteen grains equalled, in sleeping effect, about nine grains of chloral.

The dose named by writers noted is fifteen to thirty grains. I have given fifteen to sixty by mouth, double if by bowel, and fifteen hypodermically. It can be given in capsule or solution—preferably the former. If the latter, twice the amount of alcohol should be added to the elixir or syrup. By bowel, in gum arabic. Subcutaneously, direct. Convenient formulæ:

℞. Hypnal ..... ℥ xv.
Alcohol ..... ♏ lx.
Elixir or syrup ..... ad ♏ ccxl.
M. Sig.: One dose; one-third tumbler water after.

℞. Hypnal ..... ℥ xxx.
Mucilag. acaciæ ..... ʒ j.
M. Sig.: One injection

℞. Hypnal ..... ♏ xv.
M. Sig: One dose, hypodermically.

[1] Read before the Medical Society of the County of Kings, October 21, 1890.

I have used hypnal in 16 cases. The result has been: success, 10; partial success, 2; failure, 4. By failure is meant no relief from pain or insomnia; by partial success, limited or delayed sleep; by success, four to six hours' slumber. The dose has ranged from sixteen to sixty grains, in capsule or solution. Once it was given, fifteen minims, subcutaneously. The age of patients varied from twenty-eight to forty-nine years. One was a nervous, hysterical female, a ten years' taker of morphine hypodermically, eighteen grains per diem. All were exopium habitués, the extent of their daily morphine-taking varying in amount from six grains by mouth to eighteen grains subcutaneous; and in duration, four to twenty seven years. This last point is a weighty one, for expoppy habitués are notoriously insomnic.

The first dose—five minims—was taken October 1st, by myself, to determine its hypodermic eligibility. No ill result followed. It gave rise to an aching pain, short—not sharp, like antipyrine—followed by a numbness, which, in part, persists. One patient, male, aged twenty-eight, a four years' hypodermic morphine-taker, sixteen grains per day, was given, October 12th, on the eighth night of his opium abstinence, fifteen minims in the thigh. The same ache, with swelling, but no abscess, resulted, and a small anæsthetic area remains.

The hypnal never caused vomiting or nausea. Once vertigo was noted. No effect on heart or lungs. Three times—fifteen minims subcutaneously, or thirty minims by mouth—it made an unrest so great, and no sleep, that hyoscin. hydrobrom. or chloralamid was required to quiet. The average wait for sleep was sixty-six minutes; the extremes fifteen minutes and three hours and a half. The longest sleep was six hours, the shortest two. In no case was relief from pain noted without sleep. Following failure, thirty grains chloralamid promptly brought slumber. Compared with the latter—which, *en passant*, I think *the* hypnotic—thirty grains hypnal have less power than a like amount of chloralamid. As an anodyne, sedative, or hypnotic it is less effective than a combination of phenacetine and chloralamid.

The making of antipyrine being controlled by one party, under patent, which does not expire till 1906, hypnal will not come into common use, as the price is too high, my supply costing forty eight cents per drachm to import.

Through the courtesy of Dr. Edwin Reynolds, Attending Physician to the Brooklyn Home for Consumptives, four trials were made on phthisical patients. The results were *nil*. It should be said, however, that minimum doses only were used, and that the patients were such as would not warrant him in giving chloral, nor an increase of hypnal.

This is the hypnal record:

Case I.—Male. Thirty minims by mouth; asleep in sixty-five minutes; slept four hours.

Case II.—Male. Fifteen minims by mouth; asleep in sixty minutes; slept six hours.

Case III.—Female. Thirty minims by mouth; no sleep; very restless all night.

Case IV.—Male. Thirty minims by mouth; asleep in seventy minutes; slept five hours and a half.

Case V.—Male. Fifteen minims by mouth; asleep in sixty-five minutes; restless before sleeping; slept five hours and a half, with quarter-hour break.

Case VI.—Male. Fifteen minims hypodermically; no sleep; increasing painless unrest for three hours; then $\frac{1}{50}$ grain hyoscine hydrobrom. subcutaneously, with prompt quiet and sleep.

Case VII.—Male. Thirty minims; asleep in thirty minutes; slept steadily six hours.

Case VIII.—Male. Thirty minims; asleep in thirty minutes; unbroken sleep six hours.

Case IX.—Male. Thirty minims; awake and restless three hours; then thirty grains chloralamid, and four hours' sleep.

Case X.—Male. Thirty minims; sleepless unrest two hours and a half; then two hours' quiet sleep.

Case XI. – Male. Thirty-eight minims; asleep in seventy minutes; slept three hours and fifty-three minutes; awake five minutes; then forty five minutes' sleep; four hours and forty minutes in all.

Case XII.—Male. Thirty-eight minims; awake three hours; quiet when awake; then thirty grains chloralamid, and prompt four hours' sleep.

Case XIII.—Male. Forty-five minims; awake and restless two hours and three quarters; then sound sleep three hours and a half, with after report, "feeling better than for four years."

Case XIV.—Male. Forty-five minims; asleep in fifteen minutes; slept two hours; awake five minutes; then slept three hours and a half—five hours and a half in all; very quiet when awake, with morning report, "feeling unusually well."

Case XV.—Male. Forty-five minims; sleepless unrest three hours and a half; sound sleep two hours; quiet after.

Case XVI.- Male. Forty-five minims; awake two hours and ten minutes; then slept three hours and a half, with after calm.

My experience with hypnal warrants these conclusions:

Hypnotic—Fifteen to sixty minims, in most cases, efficient.

Sedative The same dose, in most cases, effective.

Analgesic—Opinon reserved.

POSTERIOR RACHITIC CURVATURE OF THE SPINE.[1]

By SAMUEL KETCH, M.D.,

NEW YORK.

It would be invidious on my part to bring before this body the description of such a well-known deformity, were it not for the fact that its clinical significance has, in my experience, been so often misunderstood. Believing, as I do, that one of the functions of the specialist is the diffusion of knowledge relating to his own particular line of work, and that this Association is a centre for such dissemination, I have taken the liberty of bringing the subject of posterior rachitic curvature of the spine before you.

Of the several deformities of the spine, whose underlying cause is found in the condition known as rachitis, the ones most commonly seen in practice are the lateral and posterior. With the first class, namely, the scoliotic, I shall not deal here, except to state that generally they are developed at a later period than the curvature, the subject of this article.

The etiology and pathology of posterior rachitic curvature of the spine are essentially those of rickets in general, the deformity being simply one of the local manifestations of a general diathesis. The causation, to my mind, is largely mechanical, and furthered by such movements tending to throw the weight of the body on the weakened vertebræ and their appendages. Rachitis of the vertebræ evinces itself, as does rachitis usually, at a very early period of life, by an irregularity in the processes of ossification, by cartilaginous enlargements, and by a marked diminution of the harder substances entering into the bone formation, notably the lime salts. In consequence of this unstable condition of the rachitic vertebræ, we find in the long axis of the spinal column many soft places, in some cases including the upper and lower surfaces of all the vertebræ, in others localized to a few. Thus the physiological firmness of the column being markedly weakened, we find a more or less extensive curvature present, depending on the number of vertebræ involved. It must not be forgotten that the other tissues—the muscles and ligaments necessary to the integrity of the column—are also involved in the rachitic process, and by their weakened action also add to the formation of the deformity.

With these few words regarding the anatomico-pathological factors, I shall at once proceed to a consideration of the clinical features, with which it is intended that this paper shall principally deal. I am quite certain that most every surgeon has at times been puzzled by the occurrence of a case which united in a marked degree the symptoms of both a rachitic kyphosis and one of inflammatory origin due to caries of the spine. It has been stated that, as a rule, the rachitic curve is a general one, embracing the whole length of the spinal column, and that a differential diagnosis in these cases was not a difficult one. However, in looking up the cases presenting at the New York Orthopedic Dispensary, I have found that the majority show a limitation of the curve to the dorso-lumbar spine, a very favorite position for the occurrence of Pott's disease. United with the localized curvature, we often have associated symptoms which closely imitate those presenting in the inflammatory cases. Thus, in addition to the deformity, we may have, in greater or less degree, pain, spinal rigidity, a pseudo-paralysis, or any of the distinctive symptoms relating to the area of disease. The pain of caries of the spine is usually so characteristic, and in the dorso lumbar region so uniformly anterior or antero-lateral, that apparently error regarding this symptom would seldom take place. It must be remembered, however, that patients the subject of rachitic kyphosis are usually very young—from one to three years old—and that they are unable to locate their sufferings accurately. That pain is not an unusual symptom in rachitic children is a well-known fact, and in many instances so acute as to prevent any handling of the patient. It is, however, general in character, and expressed by touching any part of the body, not being limited to any circumscribed spot. Again, this pain may so interfere with the muscular expression of the disease, the patient involuntarily stiffening up on attempts at examination, as to obscure the normal flexibility, and thus deprive us temporarily of a valuable diagnostic sign. In most cases of rachitic kyphosis the deformity partially or entirely disappears on placing the patient in the prone position, and there is an entire absence of that sharp, reflex muscular spasm, so characteristic on motion, and only found as the result of inflammatory bone disease. The stiffness met with in rachitic curvature due to pain may be overcome by gradual force, after allowing the patient to keep in one position for a time. Nothing short of anæsthesia will overcome the reflex muscular spasm of the bone trouble. Again, where we have a caries in the dorso-lumbar spine, we are, as a rule, able to demonstrate the presence of either unilateral or bilateral psoas contraction, which in my experience never occurs in the purely rachitic curvature. As before observed, there are cases of rachitic curvature which do not entirely disappear in the prone posture, but they are generally seen in old cases of rickets, where organic change has occurred, and are unaccompanied by muscular spasm or pain. It is not intended that this paper shall deal with either the posterior curvatures of adolescence or old age.

In connection with the rachitic deformity we are often confronted with a condition of muscular weakness so pronounced as to simulate very closely the paraplegia met with in Pott's disease. The child may already have begun to walk, when suddenly it begins to get weak in its lower extremities, and this is soon followed by an entire inability to stand. The child is "taken off its legs," or "has lost its walk," the mothers say. In other cases the child has never stood alone, nor does it make any attempt to walk. The patient, on being examined and the curvature discovered in connection with the supposed paralysis, grave apprehensions of organic spine disease are entertained. That this pseudo paralysis is not uncommon, and may be very deceptive, is proven by the fact that Berg has seen it often enough to write a monograph on the subject. This muscular weakness is not a localized

[1] Read at the Fourth Annual Meeting of the American Orthopedic Association, held at Philadelphia, September 16, 17, and 18, 1890.

one, being but another symptom of the general condition. It gives none of the characteristic electrical reactions of a true paralysis, nor do we find the consistent exaggerated tendon reflexes accompanying a pressure paralysis. Again, it is a rare thing for a paraplegia to accompany a caries of the spine when the disease is located in the dorso lumbar region, the favorite position of a posterior rachitic curve. It is always a puzzling symptom, however, and well calculated to deceive the inexperienced or superficial examiner.

I have attempted, in rather a cursory manner, to show the identity of some of the symptoms met with in posterior rachitic curvature, and also Pott's disease of the spine, and have also endeavored to demonstrate briefly the more important differential points. In closing this part of the paper, I should state that the presence of a rachitis does not preclude the simultaneous existence of a caries of the vertebræ, and that such cases are not infrequently observed. Lastly, the examination of the entire body for evidences of rachitis should never be omitted, for in the enlarged skull, beaded ribs, flattened epiphyses, etc., valuable testimony is afforded toward a diagnosis of posterior rachitic curvature.

I know of no class which are, as a rule, so amenable to treatment, and in which such grateful results may be obtained, as in those under consideration.

But I should like to protest, right here, against the very extensive prevalence of the opinion, so often given by medical men, and especially in connection with rachitic deformities, that patients will "grow out of them." Undoubtedly some cases do get well without apparent treatment, but I do not think that we are as yet in the position where we can tell positively which cases will, and which will not recover in this manner; and until such time of accurate prognosis arrives, the patient deserves the benefit of the doubt. Again, these are the class of cases in which we almost always promise a recession of the deformity, and I think that some of the marvellous cures of supposed organic kyphoses, the result of caries, were in reality puzzling cases of posterior rachitic curvature.

The treatment of posterior rachitic curvature is best embraced under three headings, namely, the general, postural, and mechanical or local, in most cases a combination of the three being advisable. Under the head of general treatment are included the hygienic, dietetic, and medicinal agents employed. I will not detain you by a lengthy account of any especial agents, as they are more in the province of the medical attendant, and undoubtedly well known to you. I should like to state, however, that my main reliance has been placed in sunlight, fresh air, the patient being in the recumbent posture, and on phosphorus and cod-liver oil internally, as well as inunctions of the latter.

In very young children, from one to two years of age, I never advise the use of mechanical supports. The tissues of these patients are so unstable that any pressure is apt to be badly tolerated, and bad sloughs easily produced. In this class the constant recumbent position, with fresh air and sun-baths, together with internal treatment and close attention to the diet, is usually sufficient.

In all cases the condition of the bowels, the urine, and the skin should be carefully inquired into. When the children are somewhat older, and beyond the more acute stages of the malady, the question of mechanical support becomes more pertinent.

Much has been written, and with some show of truth, against the use of braces in rachitic spines, and constant recumbency advised. While this latter measure is easily enough carried out in very young children, it is not so in older ones, and it is certainly better to have a child enjoy the sunlight and fresh air and exercise, with a light, well-fitting support, than to add to its already imperfect general condition the confinement necessary to one position. I confess that the indiscriminate use of apparatus, such, for instance, as are applied directly by and through the advice of instrument-makers, is to be deprecated, and the patient should only wear such supports as are constructed by the advice and under the immediate supervision of the educated orthopedic surgeon. Any apparatus having the antero-posterior leverage principle will afford efficient support. It is alone necessary that they should be light, easily adjusted, and capable of modification by the surgeon. I have personally used, with great satisfaction, a modification of the Taylor spinal brace, without the hinged pad-plate. I believe, however, the choice of apparatus, and the success attained, depend largely on the surgeon's familiarity with it.

ELBOW-SPLINT AND SHOULDER-CAP COMBINED.

By W. S. CHEESMAN, M.D.,

AUBURN, N. Y.

As a means of immobilizing both shoulder and elbow in cases of fracture at the elbow-joint, or between it and the shoulder, I have long made use of the splint whose pattern is sketched in Fig. 1. As others to whom I have shown it have also found it very useful, I make no apology for describing and recommending it.

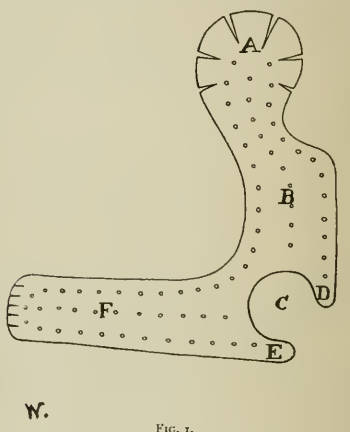

Fig. 1.

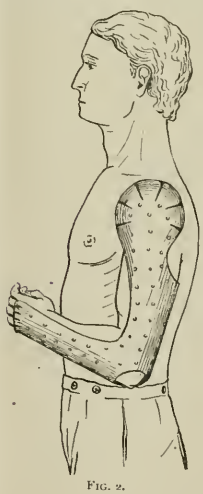

Fig. 2.

It is cut out of a single piece of tin, and its essential advantage is that it combines a shoulder-cap and a right-angled elbow-splint. In cases where shoulder and elbow must be put at rest, both these splints should be used in some form or other. It is inconvenient to splice them over a patient's arm, so the combination was made to meet the end in view.

The outline is sketched with any sharp instrument on the flat tin, the distance from A to C equalling that from the shoulder-point to the olecranon. The parts F and B are then bent (the direction of the bending depending on which arm is to be dressed) and the points D and E are riveted, a hole being thus left for the olecranon. The shoulder-cap A is made in the usual way by notching the edge deeply and bending the segments over. Their edge may be enveloped in a strip of adhesive plaster, which gives a smooth, circular rim. If desired, the whole circumference may be thus

made pleasant to handle. Perforations made with a nail and hammer, from within outward, give sharp projections which hold the bandage from slipping. The whole is lined with cotton batting. In cases of fracture of the humerus it may be necessary to employ also coaptation splints.

Fig. 2 shows the splint in position.

Clinical Department.

THE "POTATO CURE" FOR FOREIGN BODIES IN THE STOMACH.

By EDWARD PISKO, A.M., M.D.,

NEW YORK.

On the morning of December 6, 1890, an urgent call came to me to see a child, aged eleven and one-half months, which had swallowed a one-inch screw. Upon my arrival I found that the screw had passed into the stomach, so I thought it hardly possible to extract it immediately. The child was apparently well and lively, playing with the other children. In spite of the tender age of the patient and the fact that it had hardly been weaned from the mother's breast, I ordered the "potato cure." It was given potatoes in every form, and white bread dipped in milk, but absolutely no liquid food. The same evening there was a passage, and another one the following afternoon, and on the third day the baby passed urine twice, but had no passage from the bowels. The general condition was satisfactory. In spite of the abnormal food, the child played the entire day, and slept soundly every night. After the fourth day I prescribed a laxative in the evening, and during the night the screw passed spontaneously and without producing any pains, enveloped in fæces. After the evacuation of the screw, there was no injury to the stomach, no catarrh of the bowels; the child remained in its normal condition, the mishap having apparently affected its health in no way.

I mention this case to instance a successful result of the "potato cure," and also because of the interesting fact that, in spite of the unusual regimen, no visible reaction took place in an infant which had just been weaned from the mother's breast.

In connection with this case in my private practice I would like to add a few remarks about the "potato cure." Cameron, of Glasgow, relates a method which has been practised for years by English thieves, who put away all kinds of articles when caught in the act of the thieving by swallowing the same, and then they eat a great quantity of potatoes, until they rid themselves of the articles swallowed. The potato cure was first experimented upon by Billroth, of Vienna, in whose clinic I had the opportunity of watching the cases of a cook who had swallowed a part of her set of artificial teeth, of a boy who had swallowed a weight of twenty grammes, and of a girl, aged nine, who had swallowed a sewing-needle. In each of these cases the "potato cure" was applied with very flattering results. In 1886 I saw the following case in Albert's surgical clinic (Vienna): A boy, six years of age, who two years previously had swallowed a nail, which at that time was removed by gastrotomy, was brought there again with a nail (6 ctm. long) in his stomach. This time the "potato cure," which had been introduced in the meantime, was used, with the result that on the ninth day the nail made its appearance per vias naturales.

THE TREATMENT OF HERPES ZOSTER.

By MATTHEW BEATTIE, M.D.

NEW YORK.

The treatment of herpes zoster, as recommended in works on general medicine, is of no value in retarding the progress of the disease. The principal drugs mentioned are anodynes and sedatives, and the "galvanic current to allay pain." I therefore submit the following for arresting and curing this very painful disease.

Internally:

℞. Ext. gelsem. ..... fl. ʒ j.
Sod. sulphocarbolat. ..... ʒ j.
Aquæ ..... ad. ℥ iij.
M. Sig.: ʒ j. every two hours.

℞. Tr. belladonnæ ..... ʒ ss.
Sig.: Five drops every two hours until throat begins to feel dry.

Externally:

℞. Plumbi acetas ..... ʒ j.
Alum (pulv.) ..... ʒ j.
Aquæ ..... ad. ℥ iv.
M. Sig.: Apply to painful part every two hours.

On October 28, 1890, I was first called to see Mrs. W——, of West Fifty-fifth Street, and found her with a well-marked vesicular eruption, with a very red, inflamed base. The neuralgia was so severe that the patient was unable to sleep. The eruption was situated in the lumbar region and extended around the left side from the spine to the median line of the abdomen.

At the expiration of eight hours the patient was comfortable, and by November 1st (three days after my first visit), the eruption began to appear dull and the disease was positively undergoing a decline. At the end of six days the whole seat of the disease was free from pain, and the dried-up appearance of the vesicles and the falling off of the same indicated that the above treatment had been successful.

SEPARATION OF THE CONDYLOID EPIPHYSIS OF THE FEMUR.

By JOHN H. OWINGS, M.D.

E. T——, girl, aged ten years, poorly nourished and frail. On August 29, 1890, about 4 P.M., I was called to see this child, and learned that she had had her left leg caught in a wagon wheel and had suffered a fracture of the knee, with laceration of the soft parts.

Dr. Minshall was sent for, and upon placing her fully under the influence of an anæsthetic and examining the wound, we found that the condyloid epiphysis had been separated from the diaphysis, and that the shaft of the femur had lacerated the soft parts and was protruding through the integuments fully five inches.

Amputation was advised, but owing to the absence of the father in an adjoining town, the strenuous objections of the mother, and the fact that the injury had been received several hours before, and that reaction had not fully taken place, an attempt to replace the bone and make her as comfortable as possible was consented to by myself and Dr. Minshall.

An attempt was then made, only to result, to our surprise, in utter failure, to get the femur into its proper position. Dr. Douglas, who was near by, was then called in, and upon his arrival our efforts were again renewed, only again to prove futile.

By this time our patient had been under the anæsthetic fully one hour, and its beginning to have a bad effect, I advised an amputation of the end of the bone, which being concurred in by my confrères, I at once removed three-fourths of an inch of the shaft, which allowed it to be replaced easily.

My reasons for suggesting the removal of the end of the bone were fourfold. In the first place, it seemed utterly impossible to replace it; secondly, if we should ultimately succeed in replacing it there would be a possibility of wedging some one of the blood-vessels or nerves in between the epiphysis and shaft, which would be a very serious occurrence; thirdly, the fact that a good deal of periosteum had been torn off; and fourthly, believing that ossification would more likely take place if the smooth end of the diaphysis was removed, so that the

spongy portion could come in contact with the epiphysis, and therefore more likely for union to take place.

The peculiar stellate radiations of the end of the shaft were found to be perfect, except the right upper or anterior portion, which had been ground off against the hub or spokes of the wheel.

The wound, into which an ordinary orange could be inserted, was well washed with bichloride solution, and the external wound closed by ten silk sutures. Iodoform was well dusted over the parts, antiseptic dressings applied, and the limb, after flexion at hip and knee, so as to overcome the contraction of the muscles, was placed upon a pillow and left until the morrow; morphia sulph. (¼ grain) was given, and sulph. quinine (1 grain) ordered every four hours. At ten o'clock P.M. I relieved the bladder (which was causing some distress) with the catheter, and left the patient in comparatively a comfortable condition.

On the morning of the 30th the father returned, and insisted that if there was any chance of saving the leg in any condition whatever, that I should take that chance.

There being but little literature upon the subject at my command, and knowing full well that many remarkable cures had been effected, in all kinds of fractures of the lower limbs, by the use of Professor N. R. Smith's anterior wire splint, I determined to at least make the attempt and take chances.

The anterior splint of Smith was applied and the leg swung from the ceiling. At the time of the application of the splint, four o'clock P.M., the temperature was 101½° F., pulse, 130; ordered bowels evacuated by glycerine suppository.

August 31st, 8 A.M.: Bowels moved during the night. Temperature, 100⅘° F.; pulse, 116.

September 1st, 8 A.M.: Temperature, 99½° F.; pulse, 105, but intermittent; ordered tincture digitalis, 5 gtt. every four hours, quinine continued. The swelling is subsiding, patient cheerful, and suffering little if any pain.

September 2d, 8 A.M.: Pulse, 100; temperature, 99° F.; heart acting better.

September 3d, 8 A.M.: Pulse, 100, temperature normal, wound not sloughing, swelling subsiding; removed one suture to give wound chance to drain more readily, as we had not inserted a drainage-tube. Bowels not moving, ordered hyd. chlo. mite, grs. iv.; pulv. rhei, grs. v., to be taken at once.

September 4th, 7 P.M.: Pulse, 116; temperature, 101½° F.; some sloughing.

September 5th, 5 P.M.: Pulse, 108; temperature, 101° F.; bloody serum oozing from wound; removed one suture.

September 6th, 5 P.M.: Temperature, 100⅘° F.; pulse, 120; three sutures removed to day.

September 7th, 8 A.M.: Pulse, 106; temperature, 99½° F.; two sutures removed.

September 8th, 8 A.M.: Pulse, 100; temperature normal; considerable pus discharging from within wound; removed remaining sutures and applied rubber adhesive strips to prevent wound from gaping.

From this time on until October 25th, my little patient did remarkably well, suffering but little or no pain. The wound sloughed a good deal, but under the influence of a ten per cent. boracic acid with lanoline ointment healthy granulation has taken place, and the wound has filled up and cicatrization is taking place.

Desiring to know something of the result that I might expect, the wire splint is removed cautiously, and an examination of the joint made. There is comparatively no infusion of the joint proper, and some motion.

I now apply an anterior copper splint with starched bandage, and independent bandage over flesh wound.

November 14th, anterior splint removed, and one applied extending only four inches below and four inches above the patella. The wound is nearly healed; union has taken place, and there is considerable motion of knee-joint; she has been up on crutches for some time.

December 1st, flesh wound healed, crutches have been laid aside, good firm union and motion obtained with only about one inch of shortening, and my little patient walks with a cane, with very little limping, and with a firm elastic step and a good, sound leg.

Progress of Medical Science.

Femoral Salpingocele.—Dr. Von Tischendorf recently read before the Leipzig Obstetrical Society the notes of an interesting case of femoral salpingocele (*The British Medical Journal*). The patient was an elderly woman, who was operated on on account of symptoms of strangulated femoral hernia. The sac, previous to operation, appeared to contain omentum, but when opened it was found to contain the left Fallopian tube, which was much enlarged in consequence of œdema. Close to the ostium was a prominence about the size of a cherry, caused by dilatation of its walls. This prominence fitted into a corresponding depression in the hernial sac. Both tube and sac were removed, and the patient made a good recovery. Dr. von Tischendorf stated that he could only find four cases of a similar nature reported in medical literature.

The Management of the Menstrual Epoch.—Dr. A. W. Parsons, of Northampton, Mass. (*New York Medical Journal*), says: "During the past few months I have adopted a procedure which has afforded me the heartfelt gratitude of every woman who employs it. For obvious reasons its use will be largely confined to married women. A full-sized tampon of antiseptic absorbent cotton, to which a string is attached, is inserted into the vagina through a speculum as soon as the premonitory symptoms of the approaching menstrual epoch are noted. It may be left *in situ* for twenty-four hours, unless the uterine discharge begins, when it should be removed as soon as it is saturated, and the vagina washed out with a warm antiseptic solution by means of a fountain syringe, and a fresh tampon introduced. This procedure should be continued until the flow ceases. The principal disadvantage of this method is the difficulty of using the speculum and preparing and introducing the tampon; but I have met with no case where one or two lessons did not teach the woman the *modus operandi*. Its advantages are many. There is entire absence of odor, no necessity of wearing the napkin, and the sense of support to the uterus afforded by the tampon is immediate, and exceedingly grateful."

The Origin of the Amniotic Fluid.—According to Dr. Nagel, despite the industrious researches in this matter opinions are now at greater variance than ever. Gusserow bespoke favorably the theory of Portal, that the fœtus possesses the property during intra-uterine life of elaborating a urinary secretion and excretion. The conversion of benzoic acid into hippuric acid was considered sufficient proof of the functional activity of the fœtal kidneys, but this procedure of Gusserow is open to the possibility, as stated by Ahlfeld, that the conversion of benzoic acid into hippuric acid was accomplished by the placenta; although Diihrssen found in six cases that the placenta contained benzoic acid and no hippuric acid. It lies in the nature of things that the investigations of various authors embrace only the behavior of the fœtal kidneys during the last days and hours of pregnancy, and the conclusions to be drawn from such procedures are by no means satisfactory. That the kidneys may play a very insignificant rôle during intra-uterine life is proven by Ahlfeld, from the fact that, in cases where both organs are wanting, the fœtus develops uninterruptedly to the end of gestation, without the developmental anomalies going beyond their local domain.

The amniotic fluid present in such cases cannot, of course, originate in the fœtus, but it is not quite tenable to conclude that the functional activity of the kidneys under normal circumstances is unnecessary to the origin of the amniotic fluid. Nature compensates for many profound anomalies of development. It is important to subject the urinary organs—that is, the primitive and permanent kidneys—to a closer scrutiny during their first development; the researches have heretofore only taken in the condition of these organs during the latter part of pregnancy. The majority of authorities are inclined to the opinion that in the first part of pregnancy, before the development of the placenta, the amniotic fluid originates by transudation from the maternal vessels; it has hitherto been impossible to demonstrate urea in the amniotic fluid of the first months. Dr. Nagel suggests another source for the amniotic fluid—the Wolffian bodies; the latter present, during their entire existence as independent organs, the anatomical characteristics of secreting organs in full activity, justifying us in considering them as important elements in embryonal nutrition. The author then discusses at some length the anatomy of the Wolffian bodies, and illustrates his investigations with several fine plates. He concludes that at the beginning the permanent kidneys possess great similarity, in the formation of their glomeruli and the simple characteristics of the urinary tubes, to the Wolffian bodies, and that they suffice in this form to supply all the demands of metabolism at this stage of pregnancy; the human kidney is, therefore, capable of functionating in the second month of gestation, and the same applies, says Nagel, to the Wolffian bodies at a previous stage. He states that the amniotic fluid, even in the beginning of pregnancy, is in part a product of embryonal metabolism. Beginning with the subinvolution of the Wolffian bodies, the kidneys gradually assume the function of the former; for a time, before the primitive kidney has disappeared, both the provisional and the permanent organs functionate synchronously, so that the renal activity is not suddenly assumed by the kidney; before the sphincter vesicæ is so far developed as to permit the existence of a urinary bladder, the secreted urine at once flows off into the amniotic fluid.—*The American Journal of Obstetrics*, November, 1890.

Amount of Sugar in Blood in Disease.—Dr. N. P. Trinkler recently read, before the Kharkoff Medical Society, a paper on the "Diagnostic Significance of the Quantity of Sugar and Reducing Substances in the Blood," in which he detailed a number of observations he had carried out on patients in Professor Grube's surgical clinic, the majority of whom were suffering from cancer (*The Lancet*). The blood of some was taken for examination during an operation, that of the rest being only obtained after death. The examination was in all cases made by means of two processes, that of Fehling and Soxhlet, and that of Knapp (Knapp's solution consists of cyanide of mercury dissolved in caustic alkali), the mean of the two results being taken. He found that the blood during life always contains less sugar than after death, and that that of persons suffering from cancer contains a larger proportion of sugar and reducing substances than that of healthy persons, or of persons suffering from other diseases. Affections of internal organs appeared to be accompanied by a greater percentage of sugar in the blood than diseases of the skin or of external parts. The degree of emaciation produced by cancer did not seem to have any direct effect upon the quantity of sugar in the blood. There did not seem to be any real correspondence between the amounts of sugar and other reducing substances; the sugar was much more constant in its amount, the quantity of the other reducing substances being liable to very considerable variations. In the observations made on various diseased conditions the following were the amounts of sugar found: Cancer, 0.1678 per cent. to 0.2037 per cent.; typhoid fever, 0.0950 per cent.; pneumonia, 0.0943 per cent.; dysentery, 0.0838 per cent.; organic diseases of the heart, 0.0737 per cent.; peritonitis, 0.701 per cent.; phthisis, 0.0653 per cent.; syphilis, 0.0553 per cent.; nephritis, 0.0489 per cent.; hæmaturia, 0.0375 per cent.

Thyroid Grafting in Myxœdema.—The association which exists between removal or atrophy of the thyroid gland and myxœdema has suggested to some enterprising foreign surgeon to try the effect of transplanting portions of the thyroid gland in patients suffering from this malady. Mr. Horsley has shown that it is quite possible to graft the thyroid on the peritoneum in certain animals, and M. Lannelongue has attempted to apply this treatment to the case of a little girl afflicted with myxœdema. The thyroid gland of a young sheep was implanted on the child's thorax just below the right breast and took a firm hold, though whether the success of the operation will have any ultimate effect in checking the further progress of the disease time alone can determine.—*Medical Press.*

Malarial Fever and Eucalyptus Drainage.—The planting of eucalyptus trees for the purposes of draining the soil in malarial districts is one which has met with some success. The Trefontane Convent at Rome had become positively uninhabitable, owing to the malaria which attacked—in many instances with fatal results—its inmates. Senator Torelli presented a bill proposing that the estate annexed to the convent should be planted with eucalyptus as an experiment against malaria. The bill was passed, and the Trappist monks planted thousands of eucalyptus plants of all species on the estate. But still the malaria raged, and several monks suffered severely. It was, however, remarked that it was only the monks who had their cells looking on the central cloister who fell victims to the malaria. This suggested the idea of planting four eucalyptus trees at the four corners of the cloister. The plants, sheltered from the winds, soon grew to a great height. The immediate result was the complete draining of the soil in the cloister, and the disappearance of malarial fever from the convent.—*British Medical Journal.*

The Use of Hypodermic Injections of Caffeine in the Treatment of Post-partum Hemorrhage.—Dr. Misrachi highly recommends the use of injections of caffeine in cases of post-partum hemorrhages where rapid assistance is necessary, and especially when the physician first reaches the cases after there has been already considerable hemorrhage. Especially in country practice this remedy may be of great value, particularly as it is possible for the physician to have under his care cases of diphtheria or erysipelas, and to have been unable to produce such complete disinfection as would warrant the insertion of the hand. According to the author, caffeine acts more rapidly than ergot, and produces a more effective result even than ether, although the latter is a more rapid stimulant. He administered it in the form of a solution, of which a hypodermic syringeful would contain four grains of caffeine, and gave three or four injections at once—in other words, injects hypodermically about sixteen grains of caffeine. He employs caffeine rendered soluble by the benzoate of sodium, equal parts of each being dissolved in warm water. The author claims that this remedy so employed produces most remarkable results in arresting bleeding and in acting as a stimulant, and that, therefore, benzoate of sodium and caffeine in small packets should always be carried by country practitioners.—*Therapeutic Gazette.*

Experiments with Orexin.—Dr. A. Beckh describes a series of experiments with muriate of orexin. The experiments were conducted in the medical ward of the city hospital of Nuremberg, and were begun soon after those of Penzoldt. Orexin was administered to twenty two patients who suffered with loss of appetite from various

causes. A good effect was produced in seventeen cases; in one case the result was doubtful, because it was difficult to decide whether the patient's loss of appetite had been simulated or not; and in four cases the remedy failed completely. It was given to patients with anæmia, chlorosis, and tuberculosis, and to some with anorexia produced by different acute and chronic diseases. In two cases of chronic disease of the stomach it was given with very good results. At first orexin was administered in gelatin-coated pills, and later in capsules—which is the preferable way. Beckh began with doses of four or five grains a day, which were increased, as required, by the third day to seven and a half grains. A larger dose than this was not given, and a large glass of meat-broth or milk, or a plate of soup, was always taken by the patient in addition. In a few cases disagreeable effects, such as burning in the stomach, and vomiting, were noticed. Beckh concludes that orexin is worthy of further experimentation as a stomachic, and that it is to be recommended in anæmia and tuberculosis. It may also be employed with caution in chronic diseases of the stomach, but not when there exists anatomical change in the mucous membrane, as the drug is a strong irritant. For the latter reason also it must be given with a certain quantity of fluid, preferably meat-broth or soup.—*Medical and Surgical Reporter.*

Action of Living Blood on Bacteria.—Professor Bonome has recorded the results of his researches on the following points: Whether physiological alterations in the blood play any part in modifying its destructive action on bacteria; whether it is possible to produce alterations in the composition of the blood of such a nature that the normal inimical action against bacteria may be altered; and whether it is possible to derive any reliable data that will throw light on the subject of immunity. As a result of his experiments he comes to the conclusion that staphylococci introduced directly into the blood are destroyed in from ten to twenty-five minutes; more rapidly in the blood of young rabbits than in older animals of the same species. He then, by injecting the poison obtained from the pus of an old empyema or a chronic abscess in small quantities into healthy rabbits, proved that the bacteria-destroying activity of the blood is increased, the organisms used being staphylococcus aureus, albus, and citreus. He holds, however, that the introduction of such poison does not appear to exert any influence upon the similar activity of the fixed tissues. Poison from acute pus obtained in a similar manner appears to exert not the slightest influence on the destructive action of the blood; while, owing to its effect upon the tissue-elements it diminishes their power of destroying such organisms as the staphylococci above mentioned. Similar poison from pyogenic staphylococcus cultures does not increase this destructive power of the blood against the above-mentioned organisms, and any immunity that is produced depends not on the rapidity and certainty with which the blood destroys the organisms introduced into its stream, but rather upon a greater resistance which the tissue-elements exert against the bacteria poison, when they have become accustomed to the action of the poison by remaining in contact with the metabolic products of the same bacteria. He also gives experiments to show that water injected into the veins can diminish this destructive activity of the blood to a certain extent, but never completely; for, although the animals so injected and control animals died about the same time, those in which water had been injected usually showed small purulent deposits in the kidneys and myocardium, and more or less fatty degeneration of the epithelium of the kidneys, so that he considers that, in addition to this slight diminution in the destructive activity of the blood, there is some alteration of the protoplasm of the cells, probably due to the absence of salts and the cutting off of the full oxygen supply by the presence of water, by which their resistance is considerably diminished in certain areas, and owing to which they are more readily attacked by the injected staphylococci.—*The British Medical Journal.*

Points to be observed by Elderly Males.—Dr. R. Harrison offers the following advice to elderly men: 1. To avoid being placed under circumstances when the bladder cannot be emptied at will. Nothing is so bad for a large prostate, though it may be working satisfactorily, as an enforced retention. It is often the first cause of a permanent atony. 2. To avoid checking perspiration by exposure to cold, and thus throwing additional work on the kidneys. In climates like our own, elderly persons should, both in summer and winter, wear flannel next the skin. 3. To be sparing of those wines and spirits (if used at all) exercising a marked diuretic effect either by their quantity or quality; select those which promote digestion without palpably affecting the urinary organs. A glass of hot gin and water, or a potent dose of sweet spirit of nitre, will not do anything to remove the residual urine behind an enlarged prostate. 4. To be tolerably constant in the quantity of fluids daily consumed. As we grow older our urinary organs become less capable of adapting themselves to extreme variations in excretion. Therefore it is desirable to keep to that average daily consumption of fluids which experience shows to be sufficient and necessary. How often has some festive occasion, where the average quantity of fluid daily consumed has been largely exceeded, led to the over-distention of a bladder long hovering between competency and incompetency. The retention thus occasioned by suspending the power of the bladder, has frequently been the first direct step toward establishing a permanent, if not a fatal, condition of atony or paralysis of this organ. 5. It is important that from time to time the reaction of the urine should be noted. When it becomes alkaline or offensive, the use of the catheter may be necessary. When a catheter is required it is most important that its selection should not be left entirely to the instrument-maker. There are other points to be considered beyond the fact that it is to serve as an artificial outlet for the urine from the bladder. An unsuitable catheter in a prostatic case may do much permanent harm. 6. Some regularity as to the time of performing micturition should be inculcated. We recognize the importance of this in securing a regular and healthy action of the bowels, and though the conditions are not precisely analogous, yet a corresponding advantage will be derived from carrying out the same principle in regard to micturition.—*Medical Press and Circular.*

Treatment of Stricture by Linear Electrolysis.—Dr. Fort, of Paris, has operated on seven hundred strictures of the urethra without a single fatal result, by means of electrolysis (*The Provincial Medical Journal*). By means of the electroleur, an instrument invented by Dr. Fort, the operation when properly done is innocuous, without pain or blood, and no bougie is needed afterward. Dr. Fort has been the first to apply linear electrolysis in cases of œsophageal obstruction. He related the remarkable case of a young girl having so narrow a constriction that she was unable to swallow anything beyond a few drops of liquid. At the time she was at the point of death. A month afterward the disease was cured. After fifteen applications of the electroleur she was able to eat all kinds of food, and her weight increased twenty-five pounds during that time. The conclusions of the author are as follows: 1. Linear electrolysis may be used for all kinds of strictures. 2. Owing to the simplicity and harmlessness of this operation, and owing to the greater infrequency of relapses by this than by other methods, he thinks that linear electrolysis should be preferred to urethrotomy, and should constitute the operation *par excellence* in the treatment of stricture of the urethra. Combined with dilatation, linear electrolysis gives excellent results in the treatment of strictures of the œsophagus. It certainly benefits organic strictures, and it cures almost immediately fibrous or cicatricial strictures, provided that a small bougie be used to guide the electroleur.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, January 3, 1891.

PURPURA RHEUMATICA HÆMORRHAGICA.

AMONG the very instructive records of the *Transactions of the Association of American Physicians*, 1890, is a discussion of a case of the above disease which was exhibited to the society by Dr. Prentiss.

The patient, a previously healthy boy of thirteen years, was first affected in March, 1889, with swelling of all the joints, very severe pain, located chiefly in the knees and ankles (and also in the stomach, attended by vomiting), and a purpuric eruption over the whole body. The attack seemed to be due to prolonged and continuous exposure to hunger, cold, and rain. On simple nutritious diet he recovered in two weeks.

In September of the same year, after exposure to scarlatina, he had a similar attack, except that the swelling and eruption were confined to the right half of the body. He was treated with acids, iron, and quinine, with morphia for pain, and the acute trouble passed away.

In November, 1889, a notable attack occurred, with hemorrhages, slight fever, delirium, dyspnœa, and conjunctivitis. The hemorrhages were from the bowels and the bladder, and also into the skin.

Up to May, 1890, when he was presented to the society, he had relapses every four or six weeks, milder than the earlier attacks. In the interval between the attacks he was fairly comfortable and free from pain, but not perfectly well. The purpuric spots had never been absent since the first attack. The urine was frequently examined and found normal, except that it contained blood at times, and that on a single occasion there was diminution in quantity, with abundance of albumin—indicating acute nephritis. The blood was examined by a competent microscopist, but no important change was detected in it.

A feature of especial interest in the case was connected with the hemorrhage into the skin—the blood being poured out apparently between the epidermis and the corium—producing gangrene of the skin. The most remarkable of the patches were upon the abdomen, where, at each side of the navel, an ecchymosis of the size of the palm of the hand appeared and became complete in half an hour, the parts being from the beginning black and painless with true gangrene. In a few days a line of demarcation formed, and the dead tissues sloughed, leaving a granulating surface which healed with a scar. The boy had a tight phimosis, but ecchymosis with sloughing on the penis saved the trouble of circumcision.

Arsenic seemed to have done the most good to the patient, with salol for the rheumatic symptoms.

In the discussion of the case, the fact was brought out that gangrene is a rare occurrence in this disease. The nature of the changes which give rise to the ecchymosis received considerable attention. According to the observations of the members of the society, purpura, whether of the simple or of the more severe and hemorrhagic forms, is essentially the same. It may be associated with rheumatic or with nervous disturbances. The cause of the effusion of blood appears to lie, not in any change in the blood, but in abnormal conditions of the walls of the blood-vessels. If so, the treatment should be directed, especially in chronic cases, to the restoration of the walls of the vessels to their normal condition, and tissue-builders should be given, such as arsenic or phosphorus. To a boy of the patient's age the latter might be administered in the dose of $\frac{1}{100}$ grain t.i.d. in some simple oil, for several months. (A German author has asserted that he has found a peculiar bacillus in the walls of the blood-vessels in this disease.) Further examination of the patient showed that there was no disease of the heart and no enlargement of the liver, but that in all probability a subacute peritonitis—the result, perhaps, of an effusion of blood into the peritoneal membrane—was present. For this, rest in bed and cold applications were recommended.

SEA SICKNESS.

IT is a curious fact that the true nature of sea-sickness, an affection from which thousands, or perhaps even millions, of individuals, medical as well as lay, suffer every year, should be as obscure to-day as it was when man first ventured upon the sea and experienced the misery that his temerity brought upon him. Of course autopsies cannot be made, for a fatal termination of sea-sickness, apart from abortion or other possible complications, occurs only once in a green moon (as the seafarer's expression has it), yet it would seem that a careful study of a long series of cases, such as it is in the power of a ship surgeon to make, would go far in the direction of a solution of the problem and might lead to something tangible in the way of the therapy of the condition. The trouble is that the misery is so evanescent and the feeling of well-being that follows it is so marked that even those who have themselves been sufferers soon lose all realization of what they have passed through, and the well on shipboard, who would feel real pity for a friend with a sick headache, have only smiles for the sufferings of their sea-sick fellows.

Theories enough have been advanced to explain the production of the nausea, vertigo, and vomiting which are the most prominent symptoms of the affection, but none of them has answered the test of experience. It is evident enough that the stomach itself is not the starting-point of the train of evil symptoms, and of late it has been the fashion to lay the blame upon the central nervous system. Some have suggested that the irregular motion of the ship occasions a slight concussion of the brain, others that it gives rise to changes in the blood-pressure or to a commotion of the cerebro-spinal fluid, from which results an intermittent compression of the brain, and that the morbid train of symptoms observed is a consequence of those repeated slight concussions or compressions. But

these results ought to follow in whatever position the sufferer may be, yet it is a fact of common observation that one suffers much less, or not at all, if he will keep the recumbent position. Another fact that would argue against either of these theories is that, as a rule, those who follow the sea soon become accustomed to the motion of the vessel and are never sick even in the most severe storms. This would not be the case if there were concussion or compression of the brain, for it is difficult to conceive of this organ becoming so used to injury as to bear its repetition without giving any sign of suffering.

In an article recently published in the *Deutsche Medizinal-Zeitung* of September 1, 1890, Dr. Roewer, a ship-surgeon of several years' experience, advances the theory of a disturbance of the muscular sense in explanation of sea-sickness. He does not deny that the motion of the ship may cause a variation in the blood-pressure in the large vessels, but thinks it highly improbable that this momentary variation should lead to cerebral congestion. It appears to him much more likely that the morbid train of symptoms, called collectively sea-sickness, is the result of a confusion of the muscular sense. The latter, in adults, is so highly developed a sense that the individual by means of it is able to judge correctly of his position, of the nature of the ground on which he stands, and even, in many cases, of the relation of surrounding objects to himself. That the "land-lubber" suffers from confusion of this sense when at sea is a self-evident fact to one who has ever tried it. During the pitching of the vessel in a heavy sea all feeling of security is lost, the support under one's feet is removed and one feels as if he were about to remain suspended in the air, while the deck on which he is standing recedes from under him. At the same time the eye is confused by the ever-changing and irregular movements of surrounding objects, and the poor sea-sick landsman feels that he is indeed "all at sea" in respect to his surroundings.

A number of facts are adduced by Dr. Roewer in support of this theory of the essential nature of sea-sickness which do not bear out that of cerebral congestion or concussion. In the first place, we find that a person gradually becomes accustomed to the motion of the ship, educates his muscular sense so that it is no longer confused by the new order of things. Again, one is much less apt to suffer from sea-sickness while retaining the recumbent posture. In this position the body is supported, the muscles are lax, and are not taxed to maintain an equilibrium. But when, during a storm, the vessel pitches heavily some muscular effort is necessarily exerted to maintain the position assumed, and then we find that symptoms, more or less pronounced, of sea-sickness become manifested. Still another fact supporting this view is that children are less liable to suffer from the malady than are adults, and the younger the child the better is his chance of escape. The explanation of this is that the muscular sense is less developed in them than in older persons, and is consequently less liable to confusion by the motion of the ship.

Dr. Roewer's theory, which resembles in some respects that previously advanced of irregular respiratory function, is ingenious and well reasoned out by the author, but unfortunately he suggests nothing practical in the way of prevention or cure of sea-sickness. He very rightly looks upon all so-called specifics, such as antipyrine, cocaine, and the like, as worse than useless, and contents himself with the laying down of certain rules looking to a simple and moderate diet and attention to the bowels. If this theory were correct it should be possible to devise a certain plan by which, by means of suitable preliminary graduated exercises the muscular sense might become educated to a shifting base of support so that when the individual went to sea he might be, to all intents and purposes, an experienced and hardened sea-rover.

DOES SWEET OIL REMOVE GALL-STONES?

Most striking results are at times obtained from the administration of sweet oil in cases of hepatic colic. A pint or so of sweet oil (or, in some cases, of other bland oils) is administered to a patient who has been for some time suffering from this form of colic, and some hours later an evacuation of the bowels takes place with the expulsion of numerous green masses believed to be gall-stones. At any rate, the patient feels greatly relieved, and may remain free from colic for years. In the Medical Society of North Carolina an interesting discussion arose on a paper presented by Dr. Burbank (*North Carolina Medical Journal*, June and August, 1890), touching the value of sweet oil in this affection. Dr. Burbank stated positively that the green masses referred to are not gall-stones at all; that they are composed of soap (formed from the oil and the alkalies of the bile), of oil which is in excess, and of bile pigments and very small quantities of cholesterin—the latter constituent forming less than one per cent. of the green masses, whereas it forms seventy or eighty per cent. of gall stones; that examination, in patients with thin-walled abdomens, proved beyond a doubt that the gall stones felt before the administration of the oil were still present after the oil had produced its benign effects. He subjoined a brief account of three cases in which large doses of sweet oil were given. None of them presented any history of hepatic colic, yet the use of the oil was in each case followed by the expulsion of masses dark green and whitish in color. In each of these cases the administration of the oil had been preceded by a dose of calomel. In a fourth case no calomel was given, and no masses were seen in the evacuations. This seems to show that the masses are formed when the oil is met in the intestines by a large quantity of fresh bile.

In the discussion which followed many members participated. The general tenor of their remarks was as follows: There is no doubt that the administration of sweet oil does give relief in cases of hepatic colic. Acute attacks of pain should be relieved by opiates, and large doses of oil should be given as soon as quiet is obtained. In many, if not in all, cases the pain fails to recur after the oil has acted on the bowels. The masses (like bits of cucumber pickle covered with mucus) which are passed in nearly all cases are not gall-stones, but soap formed by the action of the bile and pancreatic juice upon the oil; yet, white fragments of gall-stone are sometimes passed along with these green masses, and sometimes whole gall-stones are found in the stools. Sweet oil will not remove gall-stones from the gall-bladder or bile-ducts—it is not given until cessation of pain has shown that the stone has passed

into the bowel. The presence of gall-stones in the bladder does not cause colic, nor does the passage of a small stone through the duct cause it, necessarily. It is probable that the oil acts upon the duct and the adjacent bowel in such a way as to remove the conditions which are the immediate cause of the repeated attacks of hepatic colic.

The President related the case of a man who, several years ago, suffered from repeated attacks of colic. A stone of one-half inch diameter could then be clearly felt in the gall-bladder. The attacks of pain were accompanied by distention of the bladder with bile. In each of three attacks half a pint of sweet-oil was given with benefit after the bowels had been cleared by a saline purge. Green masses were passed and the retention of gall ceased, but the stone could still be felt in the bladder.

CUTTING DOWN PHYSICIANS' FEES.

It is reported that in several counties of New York State the Boards of Supervisors have cut down the fee for the examination of lunatics from $10 to $5. Physicians do so much medical service for nothing that public officials are always quite ready to cut down the medical fees for official work to the lowest figure. The ten-dollar fee is not an exorbitant one, and will not impoverish any county of the State.

We learn that in Columbia County the physicians have combined, and have notified the Board of Supervisors that they will no longer submit to the cut rates, and will not do any work of the kind in the future for the county unless they are promised full pay. In several of the counties the matter is to be brought before the County Medical Societies, and resolutions will be offered for adoption taking the same ground that the Columbia physicians have taken. A movement is also on foot to have each County Medical Society elect delegates to the meeting of the State Medical Society, to agitate the whole matter there, and to get, if possible, the State Society to make a bold stand on the question, and to appoint a delegation to go to the Legislature and have, if possible, a law enacted fixing the rates for examining indigent lunatics at $10 each, and fixing satisfactory rates for making autopsies.

We trust that this movement on the part of the physicians will be carried out. Let the matter be agitated until strict justice is done.

COMPENSATION FOR THE DERMATOLOGIST.

Lupus cases are so rare in New York that the prime article commands a premium. Inoculators have manipulated a corner in the lupus market. Hospitals without lymph soon find themselves without the pet case of lupus they were keeping for the experiment. The office of the specialist is no longer enlivened by the variegated and patchwork features of the unfortunate victim of this wolfish disease, and a man must be foxy indeed to induce a patient to continue, at the present time, with scarifications, scrapings, burning, and other modes of torture cure. But—and here is where the cutaneous man gets it back—the lymph produces skin eruption. For every case of lupus lost he will be called in some twenty times to consult about the erythema or the dermatitis which the lymph has occasioned. We are told that a *scarlatiniform erythema*, lasting for several days, and followed by desquamation, is not uncommon, and that a papular or maculo-papular eruption, resembling measles in a measure, or an urticaria-like rash often comes on shortly after the lymph treatment is begun. The dermatologist will not yet go into another specialty, but will occupy his spare moments writing a treatise on medicinal eruptions up to date.

SENSORY SHOCKS OF THE PRÆ-DORMITIUM.

This interesting class of phenomena was first described by Dr. Weir Mitchell, and afterward commented upon by one other practitioner. Except by these two, no original observations have been published upon the subject. The disorder in question consists in the experience by the patient of a sudden and violent sensation in his head. Five varieties of this phenomena are described by Dr. Weir Mitchell, who gives, in the *Transactions of the Association of American Physicians*, 1890, a review of this and other kindred sleep-disturbances. It may be, *first*, in the sphere of general sensation, like a blow or jar, or a rending as if a bolt were driven through the head; *second*, an auditory shock, as of a loud noise, a pistol-shot, a crash of broken glass, a twanging wire; *third*, a visual sensation, as of flashes of light, vivid or like the glow of "heat-lightning;" *fourth*, an olfactory impression, as of a sudden odor; *fifth*, a class, which he adds with hesitation, of emotional discharges, in which a sudden feeling of fear is experienced before or after the sensory shock.

These phenomena are observed just as the patient is losing his consciousness in sleep. They do not occur during awakening, and are rarely experienced in daytime. All patients whom he has known to have felt them in the daytime have been hysterical. Occasionally they happen in sleep and awaken the patient.

In many cases a sensation much resembling the "aura" of epilepsy precedes the sensory shock. One patient described this as the surging upward of something—as of a wave not of air, but of something more positive. When it reached the neck a shock as of a thump on the skull or of a pistol-shot fired in the brain occurred. At any time before the wave reached the neck he could avert the shock by rising or turning to his left side (it started only when he lay on the right side). He could not check it by any mental effort. He began to make observations on this sensation only after he had become used to the alarming shocks which first engaged his attention. The premonitory sign is sometimes a tingling, rising in some cases from the epigastrium; when once felt it usually appears before each succeeding attack as long as the disorder lasts. Sometimes it is a humming or buzzing within the head. When it occurs in hysterical women it is impossible for the patient to prevent the succeeding shock, either because the preliminary sensation is too short or because it is irresistible.

The differentiation of these sensory shocks, with their preliminary waves, from the auras of epilepsy and the *petit mal* is extremely important. Dr. Mitchell dwells at length on this differentiation, but his statements are a little obscure. The main points of distinction appear to

be: *First*, the time at which the attacks occur—the sensory shocks (except in hysterical patients) occurring at the approach of sleep, while epilepsy does not haunt this period of incipient slumber; *second*, the general influence of the disorder—sensory shocks are not attended with the mental and physical disease—changes of epilepsy; *third*, the nature of the explosion—this is said to be more crude in the sensory shock, where it is a coarse sensation of taste or smell or sight or touch, than in epilepsy, where it is more definite, a particular image being seen, a well-known impression being felt, a familiar odor being smelt, or a musical harmony being heard; *fourth*, the absence of unconsciousness and of muscular spasm—in sensory shock consciousness is not lost, stupor does not follow, and no spasm occurs except in rare cases, where an uncontrollable jerk or flap of the whole body ends the attack; *fifth*, the ease with which a cure may be effected—the difficulty of subduing and preventing the recurrence of even the mildest forms of epilepsy when the paroxysms have often occurred is well known; sensory shocks, however, are much less obstinate; being associated in women with neurasthenia and hysteria, and being caused in men by overwork or the excessive use of tobacco, great benefit results from removal of the depressing influences which have brought the nervous system into an irritable condition. With respect to drugs, bromides and strychnine are most efficacious, and the sensory paroxysms yield readily to their influence.

The premonitory wave appears to be the same as the aura of epilepsy, the difference being that it leads to another sort of explosion. It is perhaps also of a more crude character than the epileptic aura.

Two cases are mentioned in which the sensory shock of light or sound (preceded by a wave-sensation) did not complete the paroxysm, but was attended by a sense of pain darting down the cervical spine and out along both arms to the finger-tips.

However closely the attacks of sensory shock may approach those of epilepsy, Dr. Mitchell believes that he has good reason for viewing them as two essentially different disorders.

A USELESS LAW.

We recorded the fact recently that our esteemed legislators at Washington had passed a law authorizing the Secretary of Agriculture to cause to be made "a careful inspection of salted pork and bacon intended for exportation, with a view of determining whether the same is wholesome, sound, and fit for human food, whenever the laws, regulations, or orders of the government of any foreign country to which such pork or bacon is to be exported shall require inspection thereof relating to the importation thereof into such country." The American hog may have septicæmia, rabies, hog cholera, in which case his carcass is totally unfit to eat; or tuberculosis, in which case there should be a careful inspection and selection of the meat; or trichinosis and some half-dozen other parasitic diseases, which make the meat dangerous. But there is not one of these disorders which an inspector can discover in salted pork without a hopelessly long microscopical search.

Dr. Olof Schwartzkoff, writing in the *Journal of Comparative Medicine*, says: "From the process of curing with salt, the meat becomes so hard and rough that it is difficult, almost impossible, to prepare it for microscopical examination." The same law contains nine long sections prohibiting the importation of adulterated food and drink.

There seems little doubt that the present food inspection law is an absolutely valueless one so far as it concerns salt pork. Nor can it reasonably be expected to allay suspicions abroad.

Still, it furnishes the entering wedge to a more general and wiser system of meat inspection, such as we believe some day will be established.

HUMAN MILK AND ITS PATHOLOGICAL VARIATIONS.

The much-discussed question of the composition of human milk and of its pathological variations, has received a valuable contribution in a recent article by Dr. T. M. Rotch (*Archives of Pædiatrics*, November). Dr. Rotch made a number of analyses of human milk taken from healthy mothers with thriving infants. He compares this with a table which represents the average of several recent analyses by different chemists. The result is as follows:

	Normal Average.	Range observed with Thriving Infants.
Fat	4	3 to 4
Albuminoids	1 to 2	1 to 3
Sugar	7	6 to 7
Ash	0.2	0.1 to 0.2
Total solids	12 to 13	10 to 14
Water	88 to 87	90 to 86
	100 to 100	100 to 100

This table shows that sugar is the least variable of the organic constituents, and that the range of variation for the fat and albuminoids is not great. In other words, healthy human milk has quite a fixed chemical composition. It was observed that when the periods between nursing were short, the milk was more condensed, a fact which throws light on the dyspeptic phenomena occurring in babies who are fed too often.

The effects of diet and exercise on nursing women were marked, but showed themselves mostly in the fat, next in the albuminoids, and least in the sugar.

Dr. Rotch gives in the following table typical analyses of normal milk from a woman leading a healthy life as to exercise and food, of poor milk (starvation), of over-rich milk (rich feeding, lack of exercise), and bad milk (pregnancy, disease, uncontrolled emotions, etc.):

	Normal.	Poor.	Over-rich.	Bad.
Fat	4.0	1.50	5.10	0.80
Albuminoids	1 to 2.0	2.40	3.50	4.50
Sugar	7.0	4.00	7.50	5.00
Ash	0.2	0.09	0.25	0.09
Total solids	12 to 13	7.99	16.35	10.39
Water	88 to 87	92.01	83.65	89.61

As a general rule, the amount of fat may be increased by increasing the amount of meat in the diet, and the amount of albumin decreased by moderate exercise.

It seems from the tables as if the main trouble in poor human milk was too little fat and too much casein.

When women take too much food and too little exer-

cise there is an excess of albuminoids. This is shown in the accompanying table. The milk was that of a healthy wet-nurse; during period I. she was poorly fed, during period II. she had rich food and little exercise for a month, and during period III. the food and exercise were regulated.

	Period I.	Period II.	Period III.
Fats	0.72	5.44	5.50
Albuminoids	2.53	4.61	2.90
Sugar	6.75	6.25	6.60
Ash	0.22	0.20	0.14
Total solids	10.22	16.50	15.14
Water	89.78	83.50	84.86

This percentage of albuminoids in the milk contained in the stomach of the child may be reduced by giving a small quantity of sterilized water during the nursing, and if it be accepted that in well-fed women taking little exercise the albuminoids are likely to be in excess, and that this excess is in itself sufficient to produce vomiting, colic, and diarrhœa, then the dilution of the milk in the stomach by water given during a pause in each nursing is a line of treatment which ought to be tried.

News of the Week.

A Protective against Diphtheria.—Dr. C. Fraenkel has published (*Berliner klinische Wochenschrift* and *Lancet*) an account of his observations, conducted by himself and Dr. Brieger, upon immunity from diphtheria. Their aim was to discover a means whereby the toxalbumin produced in the growth of the bacilli of diphtheria could be so modified as to serve as a protective agent. Without detailing the various ways in which they attempted and failed to get such a product, it must suffice to say that they found by heating the filtered culture-fluid to 60° or 70° C. it could be used as a protective agent, which, injected subcutaneously in the guinea-pig, rendered that animal free from the effects of subsequent inoculation with the diphtheria virus. As a further result of their experiments they arrived at the conclusion that the material which afforded this protection was not of the same nature as the virus itself; and that therefore the result was not due to any process of attenuation by heat. For if the culture-liquid were only heated to 55° it still retained its specific toxic property; while if heated to 100° it lost its protective qualities. The inference was that the culture-fluids contain at least two kinds of toxalbumins, the specific poison of diphtheria and its antidote, and that the former was destroyed by a slightly lower temperature than the latter. We use the word "antidote" in a general sense, for it is important to bear in mind that the material does *not* prevent the action of the diphtheria virus after this has been inoculated. If anything, it seems to hasten the fatal termination. As a protective it has, however, so far succeeded in their hands in these experimental cases. Hence, so far as can be at present judged, the discovery of Drs. Behring and Kitasato is likely to be more fruitful of beneficial results.

Demanding Fair Rates.—The physicians of Dutchess County have sent a petition to the Board of Supervisors saying that they believed $10 a just and fair charge for an examination of a dead body before a coroner, $25 a just charge for ordinary autopsical examinations, and $10 a just charge for an ordinary examination in lunacy. Then the petitioners add as follows: "We do hereby agree not to perform the duties of coroner's physician or examiner in lunacy for a less sum than above stated, and we would respectfully ask your board to fix the above charges as legitimate rates. We are forced to this action by the knowledge and belief that our services are misunderstood and our labors underrated; that our professional qualifications are gauged by the standard of the day laborer, and that often in the past no account has been taken of our skill and ability nor of the dangers we have to encounter. And we further agree that unless more definite action is taken by your honorable body, whereby we may be assured of the full payment of our bills at the rate above stated, we will decline in the future to act in a professional capacity as coroner's physicians and examiners in lunacy for the county of Dutchess."

A Medical Senator.—Among the new senators of the kingdom of Italy appears the name of Giulio Bizzozero, ordinary professor of general pathology in the University of Turin, and well known in European schools for his researches on the composition of the blood in health and disease.

Dr. A. F. Holt, Surgeon-General of Massachusetts, died December 28th in Martin, Fla. Dr. Holt resided at Cambridge, Mass., and left for the South about two weeks ago for the benefit of his health, he being a sufferer from Bright's disease. He was born in Lyndeborough, N. H., December 16, 1838. He obtained his medical education at the Harvard Medical School and University of Vermont, and served with distinction during the war as hospital surgeon. In January, 1884, he was appointed Surgeon-General of Massachusetts.

Opportunities for Medical Study by Women.—There are now forty-seven medical colleges, in the United States and Canada, which admit both sexes; and nine colleges which are for women alone.

Dr. Mackenzie Gets some Lymph.—The German doctors, who, says the *Pall Mall Gazette*, have by no means lived down their jealousy of Sir Morell Mackenzie yet, are very sore at his having obtained some of Dr. Koch's lymph, and having thus been able to make one of the earliest demonstrations in the "cure." A week or two ago it was known in Berlin that Sir Morell was trying to get some of the lymph. "But he will not get any — no, he will not get any," said Dr. von Bergmann, gleefully, to a journalist who was talking to him on the subject. But Sir Morell did get some. How did he do the trick? That is the question which is perplexing the Berlin "medicos." Only Sir Morell Mackenzie and another know, though some others have made a shrewd guess.

The Co-education of the Sexes.—The Medical College which first admitted a woman medical student, as described most interestingly by Dr. Smith, is now extinct. The lady who graduated was not Dr. Emily Blackwell, but probably her sister; Dr. Emily Blackwell graduated from the Cleveland Medical College (also now extinct) in 1854.

The Vagus Treatment of Cholera.—The *Madras Mail* states that, at the instance of the Secretary of State for India, the Government of India has forwarded to all local governments and administrations copies of pamphlets by Dr. A. Harkin, of Belfast, Ireland, entitled "The Vagus Treatment of Cholera," with a request that the mode of treatment therein recommended may be tested in selected hospitals, and the result communicated to the Government of India. The treatment is in itself remarkably simple—viz., the application of blistering fluid behind the right ear, with the idea of stimulating the vagus nerve, so as to inhibit the action of the sympathetic on the abdomen. For, from a consideration of the phenomena of cholera, Dr. Harkin arrives at the conclusion that in the inordinate action of the sympathetic we have an explanation of the violent purging, cramps, and other characteristic symptoms; and he urges, from the known physiological effects of the relations between the vagus and the sympathetic, the trial of the remedial measure above stated.

The Medical Practitioners' Protective Alliance.—The following are the portions of the code of this association which explain its objects:

"Article II. The object of this association shall be to maintain organized co-operation among the practising physicians who are legally qualified to practise in their respective States, and in good standing, for the purpose of protecting medical practitioners from the abuse of dispensaries that treat many who are well able to pay; from the unjust competition caused by short term, quick graduating, and inferior medical colleges; to endeavor to promote the passage of just and equitable laws regulating the practice of medicine in all States, so that the license to practise issued by any one State shall be valid in any other State; to devise means to enhance our financial condition (and thereby our usefulness) in every honorable way, and to derive the incalculable benefits that only can be obtained by combination and unity of action. The fees shall be $3 for first year, and $2 for each succeeding year."

"Article VII. That an effort be made to secure a law in each State that will secure the medical practitioner from the many losses he now sustains from those well able to pay, but unwilling, and to make the physician's claims, in all cases, a preferred one, which must be paid before the *pro-rata* of an estate, as is now the law in some of the most enlightened countries of Europe."

The names of those wishing to join is desired by Dr. J. H. DeWolf, 1600 Franklin Street, Baltimore, Md.

The Micro-organism of Cancer.—Dr. William Russell has made a contribution to the above subject which deserves much attention. He has found certain bodies which he calls "fuchsin bodies" in the epithelial masses of cancer. *The British Medical Journal* says: "As far as can be gathered from his paper, Dr. Russell is undoubtedly of the opinion that the organism he describes is not a psorosperm, but is one of the yeasts or sprouting fungi. He thinks, indeed, that he has been able to demonstrate in his sections the actual budding that is so characteristic of the vegetative multiplication of the yeast cells. Whatever may be the outcome of this work, Dr. Russell has placed on record an admirable method of staining, and so demonstrating certain protoplasmic bodies, which, although probably previously observed, have certainly been misunderstood; and it is quite possible that as a result of this improved method of staining some of these bodies, the structure of which we have hitherto not been able to make out accurately, and which, for want of a better name, have been spoken of as 'psorosperms,' will now have to be reclassified and spoken of as 'yeast.' Dr. Russell does not claim to have proved any causal relationship between his fuchsin bodies and cancer, but after eliminating all fallacies, as far as he was able, he places his results before his fellow-pathologists in order that his observations may be confirmed or corrected." The yeast fungi are not believed, however, to be pathogenic organisms, hence it is highly improbable that Dr. Russell's "fuchsin bodies" are causal factors of cancer.

A New Process of Cremation and Mummifying has been proposed in France, based upon the well-known and successful experiments in plating with copper or other metals, by means of electrolysis, the most delicate tissues of grasses, leaves, and skins. Certain Frenchmen have, as an experiment, actually plated a dead child. The result is a perfectly faithful statue of the subject, truer to life than any sculptor could hope to achieve. The metallic shell is strong enough to withstand shocks. To receive the electroplating of copper, aluminum, or gold, as the case may be, the skin is prepared by a bath of nitrate of silver, and the silver reduced upon it by the vapor of phosphorus. There are also various other ways of providing the necessary "electrode" on which to deposit the coating.

The New York Cancer Hospital has received the sum of $40,000 from the estate of the late Mrs. George W. Cullum.

Vital Statistics of American Jews.—The last census contains a study of the vital statistics of the Jews resident in this country. The inquiry resulted in the return of 10,618 completed family schedules, embracing 60,630 living persons; in these families there had been 2,148 marriages, 6,038 births, and 2,062 deaths during five years. The deaths reported for the five years give an average annual death-rate of 7.11 per 1,000 of population, being about half of the average rate for the general population. The expectation of life at the age of ten years, based upon the death rate for the year of 1889, is 61.11 and 56.02 years for males and females, respectively, as against 49.99 and 48.05 as calculated by life insurance companies for the general population of this country. Contrasting the birth- and death-rates for those of native-born and foreign-born parents, indicates that the birth-rate is decreasing, and the death-rate increasing with more prolonged residence in this country; but the general results indicate that the Jews here retain many of the peculiarities which have been noted among them in Europe.

Winckel on Obstetrics in the West.—*The Journal of the American Medical Association* makes the following interesting observations about Professor Winckel, of Germany, and obstetric art in the Great West. It says: "Professor Winckel seems to think that the obstetricians of the West do not know very much about pelvimetry.

At least this is the construction we put upon the following sentences that may be found on page 460 of Edgar's translation of Winckel's Obstetrics: 'When I hear statements made, such as those I often heard in America, in 1886, that narrowing of the pelvis hardly ever occurs there, I can only say that the clinical observation of normal and abnormal labor is still at a very low ebb in the whole of North America, with the exception of New York, Boston, and Philadelphia. Not alone are the majority of obstetrical wards very imperfect, but even in the larger services of this kind, for example, in the San Francisco County Hospital, they are entirely inaccessible to the student, and there is no question of the thorough working up of the material for observation there contained.' Certainly this is a statement *ex cathedrâ*. Professor Winckel's visit to the United States was of brief duration, and his reception by the profession was not remarkably cordial. In fact, until within a very recent period, he has been a comparatively unknown man in America. While in Chicago, unannounced he paid a visit to the Cook County Hospital, where he was hospitably received by one of the internes. This recent graduate never having heard of Professor Winckel, politely conducted him through the wards, and *en route* gave him some 'pointers' on the preservation of the perineum and on the conduct of labor. The attention to these instructions was so close and so marked that the young man, pleased with his attentive pupil, familiarly slapped Professor Winckel on the back, and cordially invited him to call again, to see some obstetrical operations!" While the *Journal* denies the charges made by Winckel, it advises a greater attention to pelvimetry by American obstetricians.

Hospitals not Charitable Institutions.—The distinguished President of the Medical Board of the Presbyterian Hospital of this city is quoted as saying, on the occasion of the recent anniversary of that institution, that "he did not like to hear hospitals described as charitable institutions." This has a singularly felicitous application to the hospital in question, which yet needs $350,000 to continue its good work in the rich, brown-stone district.

Death after Inoculation for Lupus.—Dr. Janisch reports in the *Wiener klinische Wochenschrift*, No. 50, a case of death in a girl of seventeen, after a single injection of two milligrammes of Koch's lymph. Local reaction had been very prompt. The injection was made at nine o'clock in the morning, and by three in the afternoon the region of the affected portion of the face was swollen, turgescent, and surrounded by a bright-red inflammatory zone of the width of the finger. The upper lip was livid. These local manifestations became more pronounced, and by the next morning the swelling had become more diffuse. The bright red had given place to a livid color, and in many places yellow crusts were noticeable. Dyspnœa came on, weakness of the heart, and death on the same evening, thirty-six hours after the injection.

Congenital Circumcision.—Dr. T. B. Nichols, of Plattsburg, N. Y., writes that he recently attended a French Canadian woman in confinement, and delivered her of a healthy boy, who on examination was found to be devoid of prepuce, the penis presenting every appearance of having been circumcised

THE LYMPH TREATMENT IN NEW YORK.

CASES AT MOUNT SINAI HOSPITAL.

Service of Dr. A. Jacobi and Dr. H. N. Heineman.

Case I. *Pulmonary.*—Injections continued up to 0.008 c.c. Temperature not above 101° F. General symptoms as at last report.

Case II. *Lupus Face.*—Injections up to 0.012 c.c. Constitutional reaction slight. Locally, steady improvement.

Case III. *Pulmonary.*—Injections up to 0.008 c.c. Appears stronger. Reaction moderate. Temperature not above 102° F.

Case IV. *Pulmonary.*—Injections up to 0.008 c.c. Somewhat paler. Decided reaction. Temperature up to 103.8° F.

Case V. *Lupus Penis.*—Injections up to 0.007 c.c. Marked constitutional reaction. Steady local improvement.

Case VI. *Pulmonary.*—Injections up to 0.009 c.c. Very slight reaction. Up and about, and cheerful.

Case VII. *Tubercular Bone Disease.*—Injections up to 0.008 c.c. No local changes yet noted.

Case VIII. *Tubercular Bone Disease.*—Injections up to 0.007 c.c. Disappearance of pain and disability of right arm after a few injections. Moderate constitutional reaction.

Case IX. *Tubercular Gland and Skin Disease.*—Injections up to 0.004 c.c. Marked reaction. Temperature high. Glands getting smaller. Sinuses healing.

Case X. *Multiple Sarcomata.*—Injections up to 0.0065 c.c. Moderate constitutional reaction. No change in glands.

Case XI. *Lupus Vagina.*—Injections up to 0.008 c.c. Constitutional reaction very slight. Locally, feeling of discomfort.

Case XII. *Tubercular Caries.*—Injections up to 0.003 c.c. Slight reaction. No local change.

Case XIII. *Tubercular Bone Disease.*—Injections up to 0.008 c.c. Feels well. No change.

Case XIV. *Tubercular Bone Disease.*—Injections up to 0.006 c.c. Very moderate reaction. Wounds appear same.

Case XV. *Tubercular Disease of Tarsus.*—Injections up to 0.007 c.c. No bad symptoms.

Case XVI. *Lupus Hand.*—Injections up to 0.004 c.c. Marked constitutional disturbance and hyperpyrexia. Locally, scaling very marked.

Case XVII. *Pulmonary.*—Injections up to 0.008 c.c. Marked reaction began only with 0.004 c.c. Otherwise as before.

Case XVIII. *Pulmonary.*—Injections up to 0.006 c.c. Reaction as before. Slightly weaker if anything.

Case XIX. *Pulmonary.*—Injections up to 0.008 c.c. Reaction mild. Cough much less. Feels well.

Case XX. *Pulmonary.*—Injections up to 0.009 c.c. Reaction mild. Still feels weak at times, but recuperates in intervals. Inoculations on third day only in one or two instances.

Case XXI. *Pulmonary*—Injections up to 0.008 c.c. Marked reaction. General appearance same.

Case XXII. *Tubercular Empyema.*—Operated upon for thoracentesis and resection. Treatment interrupted. To be resumed shortly.

Case XXIII. *Pulmonary Laryngitis.*—Injections up to 0.007 c.c. Reaction decided. Laryngitis improved. Feels stronger.

Case XXIV. *Pulmonary.*—Injections up to 0.007. Reaction more marked since. Appears well in interim.

Case XXV. *Pott's Disease.*—Injections up to 0.006 c.c. Reactions more marked lately. Slightly weaker. An extra day of delay required at times.

Case XXVI. *Epithelioma.*—G——, aged fifty-five, female, housework; admitted December 22, 1890. Epithelioma of lower eyelid, involving the entire thickness,

leaving an open ulcer. Left ala nasi destroyed in a circular manner about three-fourths of an inch in diameter. Existing for years. Old cicatrices about nose. Injected, December 23d, 0.001 c.c. Marked reaction and rise of temperature, with local swelling and slight incrustation, resembling closely the effect upon lupus.

Case XXVII. *Trachoma.*—G. R——, aged thirteen, Russia; admitted December 22d, 1890. Has had trachoma, most marked in right eyelid, for past year. Now upper and lower lid are much thickened and granular. Suspicions of tubercular nature of trachoma by Dr. E. Gruening. Injected, December 23, 1890, with 0.001 c.c. Reaction slight.

Case XXVIII. *Pulmonary.*—T. S——, girl, aged eleven, Russia; admitted December 8, 1890. History of one year's cough. Incipient phthisis at both apices. Broncho-vesicular breathing, etc. Injections up to 0.005. c.c. Moderate reaction. Feels well in interval.

The surgical cases in above list are contributed from the services of Drs. J. Wyeth and A. G. Gerster. Case XXVIII. from service of Dr. B. Scharlau. Cases I. and III. from service of Dr. A. Meyer.

December 31st.—No marked change has taken place in the pulmonary cases during the past week, save in one of the cases of tubercular laryngitis (Case XXIII.), who has gained considerably in weight and is improved markedly in every particular.

Of the cases of lupus, Case II. has received up to 0.020 milligr. of lymph—the face is steadily improving. In this case the patient is up and about; the constitutional reaction being almost *nil*. Temperature, below 101° F., always, and no general symptoms.

Cases V., XI., and XVI. are steadily improving—that in the first and last being most marked.

The cases of bone disease progress slowly. Case XII. is getting stouter and stronger daily, and her health markedly improved, although an emaciated, feeble child when admitted, in whose case the treatment was begun with hesitancy.

Case IX. of the gland disease is steadily improving. An additional case in child under two years of age (case of Dr. Scharlau) has reacted markedly to 0.0015 milligr. her temperature rising and the inguinal gland, for whose suppuration treatment was inaugurated, has, after swelling at first, been rapidly diminishing.

The case of epithelioma has reacted constitutionally and locally as markedly as most cases of lupus.

A child, aged eleven, suffering from chronic trachoma, has continued under treatment, with a view of determining the relation of this lesion to tuberculosis; the right lung is slightly involved at the apex. Only a few inoculations have been made, and no conclusion can yet be made.

I am privileged to report that, through the courtesies of a colleague, Professor Jacobi and I have been permitted to witness the effects of treatment in a case of leprosy in private practice. The case is one in a young man under thirty, and has existed for nine years. The treatment has been undertaken so recently that no decisive report can be made. The patient is isolated and cared for under circumstances of strict privacy, which make a more detailed report impossible at the present time.

CASES AT ST. LUKE'S HOSPITAL.

Service of Dr. Francis P. Kinnicutt.

During the past week four new cases have been admitted to St. Luke's Hospital for treatment by inoculation with Koch's fluid, making the total number of patients up to the present date twenty-six. They consist of two cases of laryngeal tuberculosis and two cases of lupus of the face. In one of the patients suffering from the latter disease there is evidence of unusually deep tissue infiltration and a very active ulcerative process exists. One of the cases of laryngeal tuberculosis is a particularly favorable one for study, as physical examination reveals only the slightest evidence of pulmonary disease. A brief report of a few of the cases that have been under treatment for the longest period is appended:

Case I., of previous reports. *Tubercular Infiltration of Apex of Right Lung.*—Two inoculations have been made since the last report, of 0.001 gm. each, on the 26th and 29th. The last inoculation was not followed by reaction and the strength of the dosage will now be increased. Physical examination merely reveals a decided diminution in the amount of moist crepitation over the affected area since the previous note. Weight of patient preceding first inoculation, 144 pounds. Weight at the end of the first week of treatment, 142 pounds; weight at the expiration of thirteen days, 145½ pounds.

Case II., of previous reports. *Prostatic Surface Tubercular Disease.*—An inoculation was made on the 29th of 0.001 gm. The reaction was much less severe, and of shorter duration. There is continued diminution in the pain in passing urine through the urethra.

Case III., of previous reports. *Lupus of the Ear and Contiguous Portions of the Face and Neck.*—The local reaction not having subsided, no fresh inoculations were made until the 30th, two weeks subsequent to the last. A marked change is apparent. The present appearance of the diseased tissue is described by Dr. George H. Fox as follows: The auricle is much whiter and more normal in shape and color. The patch below the ear is perfectly flat and smoother than before inoculations were made. There is now no tendency to exudation or scaling. The general hue of the affected part is that of hyperæmia rather than that characteristic of lupus infiltration.

Case IV., of previous reports. *Incipient Hip joint Disease.*—Reinoculations were made on December 23d and 27th of 0.0005 gm. and 0.001 gm. respectively. The reactions were less marked than previously. The examinations of the patient on the 29th by Dr. Shaffer is reported by him as follows: Patient examined on hard surface. Flexion practically normal. The thigh passes to its extreme limit upon abdomen. Abduction normal. Rotation in during flexion limited at about twenty degrees short of normal, and if the movement is persisted in the patient flinches slightly. Adduction approximately normal. Rotation in with thigh flexed at one hundred and thirty-five degrees fully equals the opposite joint in motion.

Patient in prone position. Extension of thigh approximately normal. Patient prone, pelvis fixed. Rotation in does not quite reach the normal. Rotation out free and normal. Patient is free from pain and walks without support, with the slight limp previously noted.

Case V. *Tubercular Infiltration of Apex of Left Lung.*—Several copious hemorrhages during October and November of present year, the last on November 12th. Numerous tubercle bacilli in sputa. Morning and evening temperature previous to inoculations normal. Seven inoculations, gradually increased as reactions ceased to be developed, have been given up to the present date, the last on December 29th, of 0.004 gm. The amount of sputa in the twenty-four hours prior to the first inoculation amounted to two ounces. The amount gradually increased subsequent to treatment to five ounces, to again gradually diminish to one and a half ounce at the present time. Physical signs show little change. Weight prior to first inoculation, 144 pounds; weight at the end of the first week of treatment, 142 pounds; at the expiration of the thirteenth day, 145 pounds. The patient's general condition is excellent.

Case VI. *Tubercular Infiltration of Apex of Left Lung; Lupus of Right Hand; Numerous Tubercle Bacilli in Sputa.*—Eight inoculations, gradually increased in dosage, have been given. Last inoculation, December 28th, 0.004 gm. Daily amount of sputum preceding first inoculation, twelve drachms; at present date, two ounces. Weight, prior to first inoculation, 118½ pounds; at the end of the first week of treatment, 118½ pounds;

after thirteen days of treatment, 120 pounds. There has been no marked improvement in the cutaneous tuberculosis. The improvement in general condition and the increase in weight in the cases of phthisis are encouraging. The results of the examination of their sputa will be given in a subsequent report.

Case VII. *Lupus of the Uvula and Contiguous Portions of the Throat, and Infiltration of the Left Anterior Nares.*—First inoculation, December 24th, 0.001 gm. A sharp reaction followed, though delayed for fourteen hours. Severe hemorrhage from the left nasal passage followed, with swelling of the right, sufficient to wholly occlude its lumen. Two small glands immediately beneath the left ear became markedly swollen and painful, with a reddening of the superficial skin. An old cicatrix in front of the left ear, resulting from the excision of a gland five months previously, became vividly red, with swelling of the contiguous tissue. The growth attached to the uvula was covered with a mucoid secretion. Two inoculations have since been given to this patient, with corresponding local reactions, the systemic disturbance being, however, less marked. The reaction at the site of the cicatrix is of much interest, as indicating the probable presence of remains of tubercular disease.

CASES AT THE ST. JOSEPH'S ORPHAN ASYLUM.

Service of Dr. Edmund Charles Wendt.

Up to the time of writing seven selected cases have received inoculations of Koch's lymph at this institution. The lymph was obtained through the courtesy of Dr. L. Weber, consulting physician to the asylum, to whom I wish here to express my thanks.

Small Initial Doses.—Most of the cases at this institution being those of younger children, the initial dose has generally been only one fourth of a milligramme, *i.e.*, 0.00025 gm. It is to be remembered that in using Koch's lymph we are employing a very powerful agent, and that we are still in the experimental stage of clinical investigation. It has not yet been demonstrated that, the larger the dose, the more powerful the effect for good; while, on the other hand, the possible harm would certainly appear to be in direct proportion to the quantity of lymph injected. In a given case the smallest dose that is capable of producing a decided reaction ought to be regarded as sufficient to inaugurate those tissue-changes upon which the curative effect of the lymph is supposed to depend. These remarks are by no means offered in a spirit of criticism of those who employ the usual 0.001 gm. initial dose. They are merely intended to call attention to the possibility of benefiting our patients without incurring the risk of unpleasant disturbances.

Time and Intensity of Reaction.—In all undoubted cases of tuberculosis the injection of lymph was followed by a febrile reaction. But the time of its first appearance, as well as its intensity and duration, were subject to wide variations. The highest temperature thus far recorded at this institution has been 104.3° F. Subnormal temperatures have not been observed. Alarming symptoms have not developed, although the malaise and restlessness of some of the children have been very marked. Signs of local irritation of moderate intensity have appeared at the site of inoculation in several cases. The injections have been made into the subcutaneous tissue of the abdomen, back, or thigh, preferably the first mentioned region.

There being such wide variations as to the manner of reaction, further tests with the lymph in presumably healthy, or at least non tubercular, cases should be instituted. It is in this way only that we can definitely establish Koch's claim, that the lymph produces its specific effects only in case there are tubercular deposits within the body. Brief notes of the cases are appended.

Case I. *Strong Hereditary Predisposition to Phthisis.*—Girl, aged eleven. Parents both died of consumption when comparatively young. Her only sister now in the last stage of phthisis, at same institution. This girl is pale and delicate in appearance. Chest flat. Cervical glands very slightly enlarged. No physical signs relative to lungs, no cough. Small eater.

December 24, 1890, 2 P.M.—First inoculation, 0.00025 gm. No reaction. Temperature normal. 25th. Everything normal.

December 26th, 11 A.M.—Second inoculation, 0.0005 gm.; 2 P.M.: Temperature, 99.2° F.; at midnight, 98.2° F.

December 27th, 11 A.M.—Third inoculation, 0.001 gm.; 2 P.M: Temperature, 101° F.; 9 P.M., 99.2° F.

December 28th.—Fourth inoculation at noon, 0.001 gm. Temperature did not rise above 99.3° F.

December 29th.—Fifth inoculation at noon, 0.002 gm.; at 3 P.M., temperature 100.8° F.

December 30th.—Sixth inoculation at noon, 0.003 gm. Temperature normal at time of injection.

The peculiar interest attaching to this case is due to the fact that our ordinary methods of examination would not permit us to say more than that the girl would be likely to have phthisis later on. But if the occurrence of distinct reaction after the injection of Koch's lymph is really characteristic of the presence of tubercle, then this girl is already in the first stage of tuberculosis. And it is precisely in this class of cases that the curative effect of the lymph will probably find its widest sphere of applicability. Until now this girl has developed no cough. In fact, apart from temporary malaise and a decided febrile reaction, the lymph has produced no appreciable effect whatsoever.

Case II. *Ozæna Scrophulosa, Lymphadenitis of Neck.*—Girl, aged nine; strumous; ulcerating eczema of nose, recurrent phlyctenular keratitis.

December 24th.—0.00025 gm.; no reaction.

December 25th.—0.0005 gm., followed by highest temperature of 99.3° F.

December 27th.—0.001 gm., followed by distinct reaction. Temperature, 100.3° F.

December 28th.—0.0015 gm., followed by rise of temperature to 102.2° F.

December 29th.—Temperature in morning, 99° F. Inoculation of 0.002 gm. at noon; at 3 P.M. the temperature had risen to 100.2° F.; at 5 P.M., 101° F.

December 30th.—Temperature in morning, 99° F.; injection of 0.003 gm.

This girl developed considerable cough, although an examination of the lungs before treatment was negative. The keratitis rapidly disappeared. Around the nose large red blotches appeared, which later resembled the erysipelatoid reaction seen in lupus.

Case III. *Hip-joint Disease* (Service of Dr. F. Kammerer).—Girl, aged three; left hip joint flexed, adducted, and fixed. Limping since one and a half year old. Previous treatment by extension. Abscess opened some time ago.

December 26th.—First inoculation of 0.00025 gm. at noon; at 2 P.M.: Temperature, 99.3° F.; at 4 P.M.: Temperature, 100° F.

December 27th.—0.0005 gm. injected; reaction to 100.3° F.

December 28th.—0.001 gm. injected; temperature remained stationary at 100° F. all day.

December 29th.—0.0015 gm. injected. Temperature rose to 102° F. in three hours. No signs of local reaction at hip-joint up to this day.

December 30th.—Temperature, 10 A.M., 99.3° F.; injection of 0.002 gr.

Case IV. *Hip-joint Disease* (Service of Dr. Kammerer).—Girl, aged five, taken ill about one year ago. Gradual development of symptoms. Extension treatment at first successful. Relapse this fall. Has failed of late.

December 26th.—First inoculation of 0.0005 gm. Highest reaction temperature 100.3° F.

December 27th.—Injection of 0.001 gm. Reaction to 102.2° F.

December 28th.—Injection of 0.001 gm. Reaction to 102° F.

December 29th.—Injection of 0.0015 gm. Temperature, three hours after injection, 101.8° F.

December 30th.—Temperature, 10 A.M., 99° F. Injection of 0.002 gm.

It should be stated that in this case the temperature did not remit to the normal point, but fluctuated between 99° F. and 100° F., even during the time when it should have been normal. No local reaction at hip-joint; movements more painful than at beginning of treatment by inoculation.

CASE V. *Tubercular Glands in Neck and Submaxillary Region; Scrofulous Affection of Eyelids and Nose.*—Girl, aged eleven Two years ago severe chorea, which yielded to large doses of arsenic (up to fifteen drops of sol. Fowleri t.i.d.). Has lost flesh lately. A few suspicious râles at both apices.

December 27th.—First inoculation of 0.0005 gm. at noon. Temperature, 2 P.M., 100° F.; 4 P.M., 101° F.; 6 P.M., 102° F.; 9 P.M., 103.2° F.

December 28th.—Second inoculation at 1.30 P.M. of 0.00075 gm. Temperature was 101° F. in the early morning (*i.e.*, incomplete recovery from reaction).

At the time of injection it was said to be normal, although I did not verify it. Temperature at 3 P.M., 102° F.; 5 P.M., 103° F.; 7 P.M., 103.3° F.; 9 P.M., 104.2° F.; 12 P.M., 104.3° F.

Scarlatinoid rash all over body developed after second injection. Glands in neck not larger than before treatment; not painful.

December 29th.—Temperature at 9 A.M., 101.2° F.; 12 noon, 101° F. No inoculation this day.

December 30th.—Temperature, 10 A.M., 99° F. Injection of 0.001 gm. at noon.

CASE VI. *Incipient Phthisis.*—Girl, aged sixteen. Mother died of consumption. Has been liable to "colds" for years. Supra-clavicular spaces sunken in; flat chest. No emaciation; slight cough. General condition fairly good.

December 27th.—First inoculation of 0.0005 gm. Slight reaction to 99.3° F.

December 28th.—Temperature normal at 8 A.M. Second inoculation at noon of 0.001 gm. By 9 P.M. temperature had risen to 101.3° F. Scarlatinoid rash over body.

December 29th, A.M.—Temperature normal. Injection at 11 A.M. of 0.002 gm. Temperature at 3 P.M., 102° F.; at 9 P.M., 102.2° F. Has developed much cough and expectoration.

December 30th.—Temperature, 10 A.M., 100.4° F. No injection.

CASE VII. *Scrofula.*—Girl, aged five. About one year ago convulsions and signs of meningitis. As she recovered it was held to be simple meningitis, although the symptoms were those of the tubercular variety. Also had pneumonia in 1889. At present pale and delicate in appearance; glands at neck enlarged. A few râles (bronchitic) on left side of chest.

December 28th.—First inoculation of 0.00025 gm.; no reaction.

December 30th.—Second injection of 0.0005 gm.

CASES AT THE NEW YORK INFANT ASYLUM, MOUNT VERNON BRANCH.

Service of DR. EDMUND CHARLES WENDT.

Two cases have received the Koch treatment thus far at this institution.

CASE I. *Tubercular Lymphadenitis of Neck.*—Infant, aged nineteen months. In the later part of November, 1890, Dr. Townsend removed some broken-down glands from right side of neck. Thick, bulging cicatrix. Some glands still enlarged. Healthy looking, plump baby.

First inoculation December 24th, 2.30 P.M., 0.00025 gm. No reaction except slight rise of temperature following day to 100.4° F.

Second inoculation December 26th, 0.0005 gm. Temperature rose to 100.6° F.

Third inoculation, December 29th, 0.001 gm. Temperature rose to 103° F. after eight hours.

CASE II. *Incomplete Resolution after Pneumonia.*—Colored woman, aged twenty three, condition previous to admission "delicate." Family history unknown. About the middle of October, 1890, she had an attack of pneumonia, from which she has not recovered. Temperature during height of attack not above 103° F. Signs of consolidation persisted, even after fever subsided. Cough with expectoration, occasional night-sweats, and deterioration of general health were observed. During month of December, her temperature became almost normal, no hectic. Two weeks before first inoculation highest temperature was 99.5° F.

First inoculation December 24th, 2.15 P.M., 0.00025 gm., temperature normal. Slight reaction to 99.6° F. but subjective symptoms more marked.

December 25th.—Slept poorly night before. Anorexia, nausea, malaise, pain in head and joints. Coughs much more than before injection. Later she vomited twice. Temperature this afternoon (*i.e.*, twenty-four hours after first inoculation of ¼ milligr.), 101.2° F.

December 26th, A.M.—Feels much better after a good night. Second inoculation of 0.0005 gm. followed by milder reaction. Temperature, 100.6° F.; considerable cough.

By December 29th temperature back to normal. Third inoculation of 0.001 gm. The area of chest dulness is larger, but auscultation shows no appreciable change. This case seems interesting on account of the race of the woman. So far as I know the lymph has not hitherto been tried on colored people, and the decided reaction obtained after a minute dose may give a hint as to caution in using Koch's liquid on blacks. It was noticeable also in this case that the defervescence of the febrile reaction was more gradual than would appear to be the rule.

CASES AT ST. FRANCIS HOSPITAL, NEW YORK.

Service of DR. GEORGE F. SHRADY.

(GEORGE A. WEYMAN, M.D., House Surgeon.)

Ten cases were treated during the past week by inoculation, and several re-inoculations were made.

CASE I. *Tubercular Knee-joint.*—Franz A——, aged twenty. First inoculation, December 24th, 1.001 gm.; reaction, 101° F., five hours after. Second inoculation, December 26th, 0.001 gm.; reaction, 101° F., eight hours after. Third inoculation, December 28th, 0.002 gm.; reaction, 101° F., three hours after. No marked local changes. Patient complains of less pain, and joint appears more supple.

CASE II. *Tubercular Wrist-joint.*—Mary S——, aged twenty five. First inoculation, December 24th. No marked reaction; 99⅘° F., nine hours after. Second inoculation, December 28th, 0.002 gm.; 100⅕° F., five hours after. Some heat in joint, less pain.

CASE III. *Tubercular Knee-joint.*—Annie B——, aged twenty four. First inoculation, December 24th, 0.001 gm.; eight hours after, 100⅗° F. Second inoculation, December 26th, 100⅘° F., five hours after. Third inoculation, 0.002 gm.; 99⅗° F., six hours after. December 31st, slightly jaundiced, otherwise well; inoculation postponed.

CASE IV. *Carious Sinus of Femur.*—Operated upon three times for progressive caries. First inoculation, December 24th, 0.001 gm.; 100⅕° F., in six hours. Second and third inoculations with 0.002 gm. each; no reactions, no local changes.

CASE V. *Scrofulous Ulcer of Groin.*—Inoculated for diagnostic purposes with 0.002 gm. After third inoculation, reaction in five hours, 100⅗° F.

Case VI. *Phthisis.*—Mrs. H—— (patient sent by Dr. L. Fischer). Consolidation of both apices, small cavity right apex. First inoculation, December 26th, 0.001 gm. Reaction 101⅗° F., six hours after. Second inoculation, December 28th; five hours after, 101⅗° F. Expectoration increased, with more moist râles. Patient expresses herself feeling much better, appetite improved.

December 31st. third inoculation, 0.002 milligr.

Case VII. *Phthisis.*—Annie R——, aged thirteen. Consolidation with commencing cavity. First inoculation, December 28th, one-half milligr. Reaction in four hours, 103° F., with nausea and vomiting.

Case VIII. *Incipient Phthisis.*—Frank K——, aged twenty. Inoculated December 29th, reaction slight, 99⅗° F., two hours after. Reinoculated with 0.002, December 31st.

Case IX. *Phthisis.*—(Patient of Dr. J. H. Ripley.) First inoculation, December 29th. Reaction in three hours, 102.5° F., and continued during day following.

Case X. *Epithelioma of Lower Lip.*—Male, aged fifty-five. December 24th; no reaction. Second inoculation, December 27th, 0.002 gm.; slight reaction. Eight hours after, 100° F., headache and nausea. Third inoculation, December 29th, no reaction.

CASES AT THE NEW YORK CANCER HOSPITAL.

As a diagnostic study for reactions after inoculation with the lymph Dr. George F. Shrady treated seven cases of cancer in the New York Cancer Hospital, on Saturday, December 27th, in the presence of Drs. Clement Cleveland and H. C. Coe. The cases were two of extensive epithelioma of the face, two of ulcerating cancerous breasts, and three of epithelioma of cervix uteri. An eighth case was one of lupus of the face. Without expectation of any but negative results, it was curious to note that in two of the cases, one of epithelioma of face and one of ulcerated breast, there was reaction (101° F.) within eight hours, and one of epithelioma of face, a slight reaction (99⅘° F.) within that period. One milligramme was used in each instance. In the case of cancer of the breast there was slight parenchymatous hemorrhage from the ulceration during the reaction. Of course no significance is placed upon these phenomena, but they were sufficiently curious to warrant a repetition of the experiments in those which reacted. Accordingly, on Tuesday afternoon, two milligrammes were administered to each of these. Time has not yet elapsed to note results. A case of lupus also inoculated (0.001 milligr.) did not respond to reaction and the quantity was accordingly doubled.

CASES AT BELLEVUE HOSPITAL FROM DECEMBER 19 TO 29, 1890.

Service of Dr. H. P. Loomis.

Total number of cases, 15. Lupus, 4; phthisis, 10; tubercular joint, 1.

Case I. *Pulmonary Tuberculosis.*—Mary D——, aged twenty-two; duration of disease one year. Under treatment ten days. Injections as follows: 0.001, 0.002, 0.003, 0.003, 0.005, 0.001, 0.001, 0.001, 0.001 gm. Each injection followed by slight reaction.

December 19th. Physical examination: At right apex, behind, expiration somewhat tubular. In front, on left, feeble inspiration accompanied by fine, crackling râles. Sputum, ʒ ij. per day; bacilli, 25 to 50 to field.

December 26th. Physical examination: At right apex, behind, tubular expiration well marked—few râles heard on coughing. Left side, in front, loud tubular expiration and abundance of large and small mucous râles on inspiration. Sputum, ʒ ijss.; bacilli, 12 to 15 to field.

December 29th. Physical signs: Well-marked bronchial breathing at both apices. In front the râles are less distinct. Sputum, ʒ j.; bacilli, 3 to 8 to field.

Remarks.—Injections in this case were followed by slight reactions, the temperature never going above 101.5° F. There has been a slight increase in weight and considerable improvement in patient's general condition.

Case II. *Pulmonary Tuberculosis.*—A. F——, male, aged twenty-four. Duration of disease, one year. Has had eight injections, as follows: 0.001, 0.002, 0.003, 0.001, 0.001, 0.005, 0.005, 0.002 gm. On admission, physical examination: At left apex there is prolonged high-pitched expiration and mucous râles both in front and behind. No râles on right side. Sputum, ʒ iij.; bacilli, 3 to field. At present, physical signs: abundance of râles on coughing on right side. Left side râles increased in number.

Sputum, ʒ ij.; bacilli, 5 to 8 to field.

Remarks.—Slight reaction after each injection. There has been no increase in weight, but patient's general condition is better.

Case III. *Pulmonary Tuberculosis.*—C. D——, male, aged forty-seven. Duration of disease, three months. Under treatment ten days. Eight injections, as follows: 0.001, 0.002, 0.003, 0.001, 0.001, 0.001, 0.001, 0.002 gm. On admission, physical examination showed: Consolidation at both apices; large mucous râles at right apex. Sputum, ʒ ij.; bacilli, 1 to field; weight, 113 pounds. Physical signs at the present time are unchanged. Sputum, ʒ jss.; bacilli, 2 to 3 to field; weight, 114½ pounds.

Remarks.—Slight increase in weight, but no decided improvement in the condition of the patient.

Case IV. *Pulmonary Tuberculosis.*—J. D——, male, aged thirty. Has had slight cough for one year. Had profuse hæmoptysis one month ago. Has had eight injections, as follows: 0.001, 0.002, 0.003, 0.004, 0.001, 0.001, 0.001, 0.001, gm.

December 19th.—Physical signs: Slight dulness in infra-clavicular space on right side; inspiration feeble, and expiration accompanied by fine crackling râles. Sputum, ʒ jss.; bacilli, 40 to 50 in field; weight, 131 pounds.

December 22d.—Physical signs: Right side in front, expiration tubular. Both inspiration and expiration accompanied by fine crackling râles. Râles also heard behind. Sputum, ʒ j.; bacilli, 50 to 100 to field.

December 29th.—Physical signs: Nearly all the râles have disappeared, only a few fine pleuritic crepitations remain. Sputum, ʒ j.; bacilli, 30 to 40 to field; weight, 134 pounds.

Remarks.—There is very little change in patient's cough, but his night-sweats are less frequent and profuse.

Case V. *Pulmonary Tuberculosis.*—J. Q——, male, aged twenty-nine. Duration of disease, three years. Under treatment nine days. Had six injections, as follows: 0.001, 0.002, 0.004, 0.003, 0.005, 0.005 gm.

December 20th.—Physical examination: On the left side feeble breathing and pleuritic crepitation in infra-clavicular space. Sputum, ʒ j.; bacilli, 15 to 20 to field.

December 22d.—Physical signs: Bronchial respiration with many râles at left apex. Numerous pleuritic crepitations in front. Sputum, ʒ ss.; weight, 118 pounds.

December 29th.—Physical signs: Bronchial respiration less distinct; râles less numerous; sputum, ʒ ss.; bacilli, 25 to field; weight, 123 pounds.

Remarks.—At present time patient coughs and expectorates less than usual. Appetite greatly improved, and general condition better.

Case VI. *Pulmonary Tuberculosis.*—M. B——, female, aged twenty seven. Duration of disease, five weeks. Under treatment ten days. Had eight injections as follows: 0.001, 0.002, 0.004, 0.001, 0.001, 0.0005, 0.0005, 0.001 gm. On admission, physical signs: Signs of consolidation at both apices; signs of cavity on the inner border of right scapula. Sputum, ʒ ss.; bacilli, 10 to 15 to field. Weight, 83 pounds. At present, physical signs: Less bronchial breathing and fewer râles. Sputum, ʒ ijss.; bacilli 10 to 15 to field. Weight, 85 pounds.

Case VII. *Lupus Erythematodes.*—H. H——, male, aged twenty one. Duration of disease, thirteen years.

Under treatment ten days. Had five injections as follows: 0.005, 0.005, 0.009, 0.005, 0.005 gm. On admission: Large, nodular, elevated red spot on each cheek. Around each spot is a large area of cicatricial tissue. No discharge. Weight, 146 pounds. At present the inflamed area is smaller, less red, more scaly, and is encroached upon by spots of healthy tissue. Face shows very marked improvement. Weight, 149½ pounds.

Remarks.—Reaction after each injection well marked.

Case VIII. *Lupus Vulgaris.*—M. F——, female, aged sixty-five. Duration of disease, sixteen years. Disease began as a small lump inside the nose, on right side, and slowly spread until it involved the external surface of the nose, cheeks, and upper lip. On admission: Entire face swollen, very red and glazed, with here and there large scabs. Near the angle of the mouth is a small tumor about three-fourths of an inch in diameter, hard and nodular. Has had six injections as follows: 0.005, 0.005, 0.01, 0.005, 0.005, 0.005. At present there is a decided improvement in appearance of face. The discharge from the ulcer on nose, and also tumor at the angle of mouth, has ceased. The redness and swelling are rapidly disappearing, and the scabs are falling off.

Remarks.—The patient's general condition has improved markedly. In this case the reactions were very marked, the temperature, after the third injection, reaching 104.2° F.

Case IX. *Lupus Vulgaris.*—D. S——, male, aged seventeen. Duration of disease, eight years. Under treatment six days. On admission entire face and anterior portion of neck involved, also index finger and dorsal surface of right hand. On the face and neck are several ulcers which are discharging freely. On the hand, at metacarpo-phalangeal joint, is an ulcer which also discharges. Weight, 87 pounds. Received five injections as follows: 0.001, 0.0005, 0.001, 0.0012, 0.002 gm. At present there is no discharge from the ulcers on the face or neck. Large scabs have formed over the ulcerated portions, and over remaining portion of diseased area large scales are falling off; there is less tension, less redness, and the ulcers are granulating. Weight, 89 pounds.

Remarks.—After the first injection of 0.001 gm. the temperature rose to 105⅕° F., accompanied by intense headache, with pain in back and limbs. The region involved by the disease appeared very much inflamed, and the ulcers discharged more freely.

Case X. *Lupus Vulgaris* (doubtful case). M. S——, female, aged sixty-two. Duration of disease, sixteen years. Under treatment ten days. On admission: Disease involves entire right side of nose and portion of face over superior maxillary bone. It is red, hard, nodular, and very much swollen. At its upper and lower borders it has broken down and has formed an irregular ulcer. Received four injections as follows: 0.005, 0.005, 0.005, 0.006 gm. Present appearance: The redness has almost entirely disappeared, there is very little swelling, and no discharge. The ulcer is healing.

Remarks.—This was a case injected for the purpose of diagnosis, the question being raised whether the changes were due to lupus or epithelioma. The reactions were well marked; after the first injection there was a marked rise in temperature, the diseased area became greatly inflamed and a copious discharge appeared on the ulcerated surface. This, together with the subsequent marked improvement of the case, we consider sufficient to warrant us in making the diagnosis of lupus.

Case XI. *Tuberculosis of Shoulder-joint.*—T. M——, male, aged twenty-eight. Duration of disease, two years. Under treatment, ten days. Received four injections, as follows: 0.002, 0.004, 0.009, 0.005 gm. On admission, considerable pain on motion, limited motion, and free discharge of pus. At present, no pain on motion, very little discharge, joint freely movable.

Remarks.—Slight reaction after each injection.

Case XII. *Pulmonary Tuberculosis.*—G. G——, male, aged nineteen. Duration of disease, three months. Under treatment, eight days. Received seven injections, as follows: 0.001, 0.002, 0.0005, 0.0005, 0.0005, 0.0005, 0.0005 gm. On admission, physical signs: Consolidation and infiltration at left apex; signs of cavity at right apex; sputum, ℥ iv.; 5 to 10 bacilli to field. Present physical signs: Signs of infiltration less marked, râles disappearing, cavity the same. Sputum, ℥ iijss.; 2 to 3 bacilli to field.

Remarks.—General condition of patient improved. The advance of the tubercular process in the lungs, which on admission was rapidly progressing, appears to be checked.

Case XIII. *Pulmonary Tuberculosis.*—J. O——, male, aged thirty-two; duration of disease, three years; under treatment, five days; had five injections, as follows: 0.001, 0.002, 0.001, 0.001, 0.002 gm. Physical examination: Consolidation at both apices, with pleuritis below right scapula; sputum, ℥ j.; no bacilli; weight, 115½. At present physical signs: Many moist râles developed, evidences of consolidation more marked; sputum very little; bacilli, 1 to 2 to field; weight, 117½ pounds.

Remarks.—Slight reaction followed each injection. At present no decided improvement in condition of patient.

Case XIV. *Pulmonary Tuberculosis* (?).—J. L——, male; aged forty-five; duration of disease, one year; under treatment, ten days; has had six injections, as follows: 0.001, 0.002, 0.004, 0.003, 0.005, 0.008 gm. Physical examination on admission: Signs of cavity at right apex; broncho-vesicular breathing at left apex; sputum, ℥ ij.; no bacilli; weight, 135 pounds. Present condition: Physical signs unchanged; sputum, ℥ jss.; no bacilli; weight, 136½ pounds.

Remarks.—No reaction from any of the injections. No change in general condition of the patient.

Case XV. *Acute Pulmonary Tuberculosis.*—M. D——, male, aged thirty-eight. Duration of disease, six weeks. Under treatment, six days. Received five injections, as follows: 0.00025, 0.00025, 0.00025, 0.00025, 0.00025 gm. Physical examination: On admission, consolidation at both apices, large and small mucous râles with crepitating frictions over both sides of the chest; sputum, ℥ j.; 40 to 45 bacilli to field. At present, râles more sticky and less troubling in character.

Remarks.—Patient treated upon principle of repeated small injections. Results very favorable. Patient has less dyspnœa, less cough, and shows marked improvement in his general condition.

In all but one of the cases treated, there were distinct reactions. These reactions consisted, in all cases, of rise in temperature, headache, pain in back, joints, and chest, restlessness, and loss of sleep. In some cases where the injections were large there was a slight chill. In nearly every case there has been an increase in weight, and in the phthisis cases, after the first one or two injections, a marked change in the physical signs, sputum, and number of tubercle bacilli. In lupus there is distinct improvement.

CASES AT THE POLYCLINIC HOSPITAL.

Service of Dr. H. N. Heineman.

(Assisted by Dr. F. S. Mandelbaum of Mount Sinai Hospital.)

(Reported by S. S. Davis, M.D., House Physician.)

There are five cases now at the Polyclinic Hospital, three for pulmonary tuberculosis and two for lupus. Of the three cases of pulmonary tuberculosis, one is complicated with laryngeal trouble, and all three are well advanced into the second stage. Two of them came in December 16th, and one December 27th. Of the first two, eight injections have been made, beginning with 0.001 milligr. and increasing 0.001 milligr. each time, till 0.008 milligr. has been reached. The temperature in these two cases has never been above 100° F., generally reaching its maximum in from four to six hours after the injection,

and declining again to normal within the next four hours. In one case the temperature was subnormal after the fifth and sixth injections, reaching at one time as low as 96.4° F., followed by well-marked chill. In all three there is slight enlargement of spleen, with headache and a general feeling of malaise, after each injection. Cough and expectoration was increased at first, and the general appearance and appetite is better.

Tubercles were found in the sputa in all the cases.

Of the lupus cases, both are lupus vulgaris.

Case I.—Italian boy, aged eight years, has had the trouble four years. Reaction came on in ten hours. The region involved by the disease was elevated and reddened intensely, the redness extending about two lines beyond the diseased part. In thirty-six hours the redness began to disappear, finally fading out, leaving the diseased part scaly and less elevated. He received 0.00075 milligr. for first injection, and 0.001 milligr. for second injection, which was followed by same characteristics as first, temperature never going above 99° F.

Case II.—An old lady, who has had the disease for forty years, was received December 29th, and an injection of 0.001 milligr. was made. In four hours reaction set in, with characteristic redness and pricking and burning sensations in the part affected. Spent sleepless night and complains of sense of weight. Temperature, fifteen hours later, 100.4° F.

December 31st.—Cases I. and II. are progressing, particularly Case II., with laryngeal trouble, having a generally improved appearance.

Case III., pulmonary disease in female, aged twenty-seven, of phthisical family. Disease advanced to stage of cavity. Treatment by request. General condition exceptionally good and spirits likewise. Only a few inoculations to date.

Case IV., Italian boy about eight years of age. Lupus of nose involving the lower third, also three isolated spots on back of right thigh. Reactions as usual.

Case V., lupus in elderly female, seventy years of age, existing since her twenty-third year (forty-seven years ago). Entire left cheek beneath the chin and slightly extending up on lower part of right cheek, involved in moderately deep-seated cicatricial tissue with underlying nodules. Inoculation of 0.001 milligr., followed by excessive swelling and pain locally. Constitutional reaction slight. Has received only one inoculation.

Case I. *Pulmonary.*—Injections up to 0.006 c.c. Moderate reaction. Subnormal temperature. Epistaxis. Is bright and unaffected as to strength.

Case II. *Pulmonary Laryngitis.*—Injections up to 0.006 c.c. Reaction slightly greater. Epistaxis. Spleen large. General condition same. Larynx appears slightly improved.

The Black Death in England.—As regards the effect of the Black Death upon the social and industrial system of England, Dr. Cunningham agrees to a large extent with Mr. Thorold Rogers, but with respect to its destructive influence upon the population he occupies a middle ground between the latter writer on the one hand and Mr. Denton on the other. The terror which the Black Death caused is visible in the extraordinary change which was brought about at this epoch in the artistic representations of death; the horrors of the actual visitation can be faintly indicated by statistics. The chief sources of statistical information are, for larger areas, the records of the institutions of clergy to benefices, and, for particular villages, the records of the court rolls. While the former documents seem to show that, with all allowances for the ordinary death-rate, more than half the parish priests died during the year (1348), the latter give instances where whole villages were practically annihilated. In Dr. Cunningham's opinion we shall not be far wrong in saying that nearly half of the population were swept away at this time.—*New York Sun.*

THE LATEST DEVELOPMENT OF THE LYMPH TREATMENT IN BERLIN.

[The following letter, sent to the Medical Record by Dr. Frank Fremont Smith, of St. Augustine, Fla., who has been studying Koch's methods in Berlin, contains interesting and practical facts bearing upon many points which have been subjects of discussion, and brings our information to the latest date.]

Berlin, December 15, 1890.

The American surgeon who after four hours of observation in the wards of Von Bergmann and Gerhardt set out for home, declaring that he thoroughly understood the Koch treatment, would hardly have hazarded a judgment so rash had he spent the past three weeks in Berlin. Each day has revealed new phases, and experience is teaching variations from the results obtained in the early study of the treatment.

I. Reaction.—It now seems that reaction, even in true tuberculosis, is not invariable. This was shown by Rosenbach, of Breslau, in a report, December 4th, of five cases, each with bacillus in sputum, one of them with intense lung affection and excessive bacilli, which were treated without reaction, and was stated by Krause, in private demonstration, on December 9th. A case was shown by Weber (Gerhardt's wards) December 13th, with tubercular bacillus in sputum, who has given no typical reaction with five injections, the last dose being 1 ctgr.

II. Other Tissues Susceptible.—It is recognized that tissues affected by another than the tubercle bacillus may be susceptible to Koch's fluid. There were reported, December 11th, by Bardeleben, of Berlin, one case of leprosy, and one of rodent ulcer, in both of which good reactions and improvement followed exhibition of Koch's lymph. A case of leprosy was reported by Isaac, of Vienna, December 11th, in which similar decided reactions occurred. On the same date a case of leprosy is reported by Arning, in Engel-Reimer's Hospital, Hamburg, in which 5 milligr. produced prompt and high reaction, but no local sign. It must be remembered that bacilli of tuberculosis and leprosy may have existed side by side, as in the private practice of Arning two cases of the classical form of leprosy failed entirely of general or local reaction.

III. Dangerous Symptoms.—Unsuspected tuberculous areas, brought out by the selective power of the lymph, may produce alarming or dangerous symptoms.

1. *Brain.*—Henoch has in the past week denied the advisability of making injections in cases of tubercular meningitis, deaths having occurred during reaction. In the autopsy of a case of Henoch, Virchow stated that the amount of blood in the brain exceeded any previous experience.

2. *Larynx.*—Krause warns of necessity of laryngeal examination before injection, lest sudden swelling or rapid cellular infiltration of a susceptible mucous membrane may produce complete closure. Two cases in the wards of Senator, two in those of Cornet, and one in Gerhardt's, wear tracheotomy tubes in testimony.

3. *Lungs.*—An adult patient was observed in Gerhardt's wards, December 8th, with infiltration of the left apex and bacilli in sputum. After the first injection the *right* apex, before normal to percussion, presented marked dulness down to the second rib. This passed off with decline of reactive fever. It occurred during the reaction of the two succeeding treatments, ceased with the fourth, and has not returned.

In the same wards an adult female is shown, who, after her second injection (1 ctgr.) suddenly developed distressing dyspnœa—respirations 60, 68, and 64 on the three following nights; temperature, 104° F.; absolute dulness over the lower angle of the right scapula as large as the palm, with crepitant râles. She remains under treatment, suffers no more distress, and has made a gain of two and one-fifth pounds during the past week, eight having been lost during the period of dyspnœa.

Kast, of Hamburg, December 11th, reports case of a female adult, with extensive lung tuberculosis, who was treated with gradually increasing doses, which were well endured until an injection of 15 milligr. was reached, when suddenly, during reaction, she fell into collapse. Only hypodermic stimulation prevented fatal issue.

Weber (Gerhardt's clinic) demonstrated, December 13th, a male adult, who had suffered one hæmoptysis before admission. The first treatment was on November 20th, the beginning dose 2 milligr. On November 28th, during reaction following dose of 1 ctgr., an abundant hæmoptysis occurred. Treatment was now discontinued till December 3d, since which time it has been regularly pursued without accident, and with general improvement. The patient's own statement, notwithstanding cessation of hectic and night sweats and gain of three pounds in the past twelve days, is that he "holds not much faith of the treatment."

4. *Heart.*—In Leyden's wards Dr. W. C. Bailey showed a male adult with pulmonary tuberculosis in second stage. Injections from November 12th to 26th, with doses from 1 milligr. to 1 ctgr., gave usual decided but mild fever reactions until 1 ctgr. was reached, when the temperature mounted to 104.2° F., and pulse, before running regularly between 72 and 80, leaped to 140. The patient was in great danger of heart failure for six hours. Cases of sudden heart failure and death have occurred. The best authorities here do not consider the remedy cumulative.

5. *Kidneys.*—Rosenbach, of Breslau, reports lymph injection for tuberculous ulceration of intestines, with reaction 104.5° F., in which the urine, before normal, was reduced to 50 c.c. in twenty-four hours, was dark brown, loaded with casts, entirely coagulable. This result is supposed to have been due to development of latent renal tuberculosis, or to kidney idiosyncrasy.

6. *Intestines.*—Children frequently suffer considerable diarrhœa during the early treatment. This usually corrects itself with cautious dieting, and the system becomes tolerant. In Leyden's wards (Charité) was seen, on December 11th, an adult male, with pulmonary tuberculosis who has taken six injections, during each reaction suffering intense pain in one small area of the left hypogastrium, requiring opium. He has intense reaction to the moderate dose of 5 milligr. Diagnosis of probable intestinal tuberculosis is made by Leyden.

The sudden death of a case under Stricker, of remarkable similarity, has led in these wards to the most cautious employment of the lymph, in both amount and frequency of administration.

Professor Nicoladoni, of Innsbruck, reports the case of an adult, with lupus of face, legs, and arms, not extensive; tubercular infiltration of both apices, and diarrhœa, whose temperature in eight hours after the first injection, dose 2 milligr., reached 105.8° F., and who fell into collapse and died.

Post-mortem examination: Swelling of intestinal mucous membrane and ulcerations extending to the peritoneal coat.

In concluding I might add that P. Guttmann, Director City Hospital, Moabit (Berlin), on December 11th, reports that the cases of two young female adults, with most marked symptoms of incipient pulmonary tuberculosis, both presenting bacilli in sputum, and who each received 5 ctgr. as final injection, "are to be regarded as cured under the treatment."

Since Von Bergmann reserves till January any definite opinion concerning permanent results in lupus, the form earliest treated and most watchfully observed, I shall not presume to draw conclusions.

In the present formative state of opinion it is unwise to attempt an ultimate verdict as to the extent of application of this remedy and the permanency of present hopeful results, which time alone makes possible.

NOTE.—Most of the cases reported from Berlin have been under personal observation, those from other cities may be found reported in recent issues of *Deutsche Medicinische Wochenschrift*, *Berliner Klinische Wochenschrift*, and *Deutsche Medicinal Zeitung*.

Reviews and Notices of Books.

WOOD'S MEDICAL AND SURGICAL MONOGRAPHS. Volume VII. No. 2. Contents: MORBID BLUSHING: its PATHOLOGY AND TREATMENT, by HARRY CAMPBELL, M.D.; ALCOHOLISM IN WOMEN, by DR. THOMEUF; THE DIFFERENT METHODS OF LIFTING AND CARRYING THE SICK AND INJURED, by G. H. DARWIN, M.D.; TREATMENT OF INGROWING TOE-NAIL, by JOSEPH AMIARD, M.D.; CHRONIC BRONCHITIS AND ITS TREATMENT, by WILLIAM MURRELL, M.D. August, 1890. New York: William Wood & Co.

"MORBID Blushing: its Pathology and Treatment." At first thought it does not appear that there is aught of interest or value to the physician in the subject of "Blushing." Dr. Campbell, however, finds enough to interest us through some ninety pages of this number. The question is considered from every possible stand-point; numerous cases are cited, and many illustrations add to the interest of the paper.

"Alcoholism in Women." Dr. Thomeuf's observations were based upon the inhabitants of Brittany, and the cases collected chiefly from the female wards and maternity of the Hôpital de l'Orient. Alcoholism is divided into acute, chronic, and subacute forms; and the writer devotes especial attention to the subacute form, which has hitherto been passed over with but slight mention by writers on alcoholism in women.

"The Different Methods of Lifting and Carrying the Sick and Injured." It is not an uncommon state of mind among the students of an ambulance or "first-aid" class to think that when a pad has been well and accurately placed upon a wounded artery, or some cleverly improvised splints adjusted to a broken limb, or some other injury bandaged, the work is finished. This is not so. Sometimes, and by no means infrequently, it will happen that the most difficult part remains to be done, and that is to discover how best to remove the injured person. It is to assist in reaching this end that the present paper is written. It gives carefully the necessary details, and is generously illustrated.

"Treatment of Ingrowing Toe-nail." The method described is that of Dr. Th. Anger, and consists in the removal of an oblong piece in such a way that it includes all the diseased tissues, exuberant ulcers, the border of the nail, and the corresponding matrix, at the same time leaving a flap to cover the cut surface and shorten the period of healing by granulation. In that the operation has an advantage over that of Cotting, of which the author seems not to have read.

"Chronic Bronchitis and its Treatment." This number closes with a very readable paper on that most obstinate affection, chronic bronchitis. After discussing the conditions under which it is most often found, and the symptoms, Dr. Murrell goes on to a consideration of the treatment by ipecacuanha and other sprays, tar and its allies, pure terebene and its allies, cheken and cubebs, chloride of ammonium inhalations, and fuming inhalations. The paper is enriched with numerous cases illustrating the various plans of treatment.

A DICTIONARY OF PRACTICAL MEDICINE, BY VARIOUS WRITERS. Edited by JAMES KINGSTON FOWLER, M.A., M.D. Sixty-five Illustrations. 8vo, pp. 968. Philadelphia: P. Blakiston, Son & Co. 1890.

IF one must have a medical dictionary of this sort, this volume will be found as unobjectionable as any, and more handy than most. The list of writers includes very many names already well-known among the rising generation of physicians, the articles are well condensed, and the book-making good.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 16, 1890.

ALFRED L. LOOMIS, M.D., PRESIDENT, IN THE CHAIR.

Hydrophobia: Its Clinical Aspect, by L. C. GRAY, M.D. (see p. 6); its Pathological Aspect, by C. L. DANA, M.D. (see p. 3).

DR. HAROLD C. ERNST, of Boston, was invited to open the discussion. He said that soon after Pasteur's first experiments were announced some rabbits were sent him from which he carried out a prolonged series of inoculation experiments, studying not only the virus as it was transferred from one animal to another, but trying to satisfy himself whether the method had any protective value or not. He began as a complete sceptic, not believing even that there was such a thing as rabies, but at the end of his studies he had become a complete convert to Pasteur's views. If there was anything at all which was certain it was that the inoculation of the virus under the healthy dura mater in rabbits was followed in an exact time by certain symptoms. He had never seen anything to be compared with it in exactitude in the way of experimentation.

The Term Hydrophobia Inappropriate.—He wished to emphasize the inaccuracy of the term hydrophobia. He had seen during the past year two cases of true rabies in man, and about sixty cases of true rabies in dogs, and from this clinical experience he could say he had not seen hydrophobia, or fear of water. Contraction of the muscles of the jaw and pharynx was brought on by the sight of glittering objects or the thought of swallowing, but not by fear of water. One of the men, who was perfectly rational between the spasms, said he had no fear of water at all, but that the contractions were brought on involuntarily whenever anything brought to mind the idea of swallowing.

Difficulty of Diagnosis.—He did not consider himself, nor others with whom he had been associated, competent to make an absolute diagnosis of true rabies in man or animals without inoculation experiments.

There may be Spurious Rabies.—He had been rather surprised at the statement by one of the readers that there was no such thing as spurious rabies, or that there could be no change produced in the tissue elements by the exercise upon them of the influence of the nerve-elements of thought and will. That assertion, he thought, was very flatly contradicted by a case which he had seen during the summer, and to which he referred again later.

Pathology.—Eight or nine years ago, he said, Fitz, of Boston, gave the results of microscopic examination of the spinal cord in two cases of rabies dying in the Massachusetts General Hospital. The changes were similar to those seen in the two cases which died in Boston last summer. In the first place, any change whatever that had been observed in the brain or cord in these cases had been limited to the posterior portion of the medulla or cord. Second, those changes had been much more numerous in the medulla than in the cord. In certain portions of the cord they had not existed at all. They consisted, with pretty general regularity, first, in infiltration of the walls of the vessels with indifferent white cells, making an appearance on cross section of the vessel as if the wall was stuffed with these stained nuclei. The next thing constant was the very great engorgement of the vessels, particularly of the veins. The engorgement sometimes went so far that the blood-cells could not be distinctly differentiated, presenting almost the appearance of a thrombus. There were occasional perivascular hemorrhages. These changes were evidently recent. Lastly, Fitz found small miliary abscesses. He said it might be doubted, however, whether true abscesses were present, for the leucocytes preserved their distinct individuality, were separated by an interval, and occasionally a giant cell would lie unaltered in the midst of these small foci of corpuscles. Fitz's conclusion from these cases was that the appearance indicated a miliary bulbitis; perhaps they should be called cases of acute miliary bulbitis, to distinguish them from cases of miliary bulbitis already described by Leyden. That corresponded exactly with what Dr. Ernst had found, so far as he had gone, in the two cases last summer. He exhibited microscopic sections. The first section showed a longitudinal section of a vein with perivascular hemorrhage, the second section, loaned by Dr. Fitz, showed a cross section of a vein, with thrombosis, perivascular hemorrhage, and marked infiltration of the vessel-wall.

Recent Cases.—The first case was that of a man who was bitten by his own dog last spring. The wound healed kindly. At the end of about twenty days he began to show symptoms which the attending physicians said appeared to be those of acute mania. One only of the consultants thought of rabies. A post mortem was made and the brain was submitted to Dr. Ernst for examination. Rabbits inoculated in the usual manner died of the usual symptoms.

Another case was remarkable because of the marked character of the intervals of lucidity between the paroxysms. It occurred last spring in a man who was bitten by a pet dog which had been lost for a week. The symptoms developed twenty-four days after the bite and terminated fatally in thirty-six hours after entering the hospital. The young man had previously been perfectly healthy. He was conscious during the paroxysms, so he said, as well as between them, but was unable to restrain the outbursts.

A third case was in a man who was bitten on the hand on July 4, 1890, by a bulldog while it was fighting a setter. He had no suspicion that the dog was mad, but next morning the animal's collar was brought back by a farmer who said he had killed the dog because it was biting his pigs. There were six pigs in the pen, five of which died within six weeks of, probably, rabies. The setter died within about five weeks. On the 15th of September this man was brought to the City Hospital, no question of rabies having entered his mind until twenty-four hours after his admission. He died on the 16th, the symptoms having lasted altogether about three days. Autopsy next morning. Rabbits inoculated in the usual way died in the usual manner.

A Case of Pseudo-Hydrophobia.—In July a well-nourished, ignorant Irish girl was bitten late Saturday afternoon by a dog which was running by. Sunday afternoon, or within twenty-four hours, she had every symptom of newspaper rabies—frothing at the mouth, biting the tongue, trying to bite her friends, fear of water, and on Monday came to the Massachusetts General Hospital. Unfortunately, while arrangements were being made to give her a hospital bed, somebody showed her some water and she ran away, not to put in an appearance again.

Patients Treated.—A boy in Fitchburg, Mass., was bitten in August by a dog which within fifteen minutes also bit three dogs. The father thought nothing about it, although the dog was killed the same day. Nineteen days afterward two of the three dogs died, after attempting to bite other animals. Then the father became frightened and came to Dr. Ernst for advice, who sent the boy to New York where he was inoculated. He had not and has not had any symptoms. But before he got home the third dog died of unquestionable rabies.

Rabies Epidemic about Boston.—During the years 1889-90 over sixty dogs had been brought to the veterinary hospital at Boston with rabies. Dr. Ernst tested about twenty by the inoculation method, and, the results in all being exactly similar, felt justified in considering the remainder as cases of true rabies without making inoculations. The epizootic seemed now to have died out. One curious fact was to be noted, namely, that none of

these animals, provided they were kept under quiet conditions from the time of the bite, showed the slightest symptom of furious rabies unless there was some external excitement. When let alone they simply showed the paralytic symptoms of dumb rabies and died. He was therefore led to believe that a true rabies was not a furious rabies unless there had been some external excitement. This, however, was likely to be present if the dog were running at large.

Pasteur.—Whether Pasteur was right or not, he thought there was at least one thing made out definitely, namely, that he had got hold of a specific virus, something which could be transferred from one animal to another by inoculations, always producing the same symptoms. Here was the fallacy in the experiments of Dr. Spitzka. He had produced, the speaker believed, something similar to the appearance of rabies in rabbits [the word rabbits used inadvertently for dogs, H. C. E.], but they had not been carried on far enough to offer any ground for comparison with Pasteur's work. Then there was never any suppuration produced by Pasteur's method, at least not visible to the naked eye, as has occurred in cases quoted by his opponents. There could be no fault found with Pasteur's statistics. They came out every month, and the cases were divided into classes A, B, and C, the first being where the animal inflicting the bite was shown to be rabid by inoculations, the second where it was said to be so by a veterinarian, the third where it was suspected. In class A the percentage of mortality in man after inoculations was only 0.98. There were no previous definite statistics with which these results could be compared.

Dr. W. R. Birdsall said he had never seen a case of true rabies, but had seen a number of cases of pseudo-rabies from fright, excited by the bite or scratch of a dog. None died. Yet he would not go so far as Dr. Dana and say that death from shock was impossible. Not that he believed it would prove immediately fatal, but that it might lead to changes producing exhaustion, coma, and death. A number of hysterical cases, he thought, died in this way. He thoughf it was ridiculous at the present time to deny the existence of rabies. Yet it might be a question whether there were not a number of specific germs producing somewhat similar symptoms instead of a single one. In attempting to carry out the inoculation treatment there was danger, he thought, of increasing the number of cases of pseudo-rabies, and also a possibility of introducing the poison now and then, although some denied this.

Two Autopsies.—Dr. H. P. Loomis said he had made an autopsy on two patients who were supposed to have died of rabies. One was made long before Pasteur's method was introduced; in the other the autopsy was made last December, and experiments according to Pasteur's method would show that it was a case of true rabies. With the exception of slight pulmonary œdema no changes were anywhere recognizable by the unaided eye. Microscopical examination showed in the lower portion of the medulla oblongata capillary congestion and giant cell infiltration; no capillary hemorrhages, no thrombi. The clinical history stated that the boy had been perfectly well until within four days of his death, when he became suddenly violent and delirious, grew steadily worse, and was sent to the pavilion for the insane at Bellevue Hospital, where he had spasms, threw himself upon the floor, had a wild look, the conjunctivæ congested, face alternately pale and flushed. Soon after admission he suddenly died, showing some symptoms of asphyxia. The physicians in the hospital made the diagnosis of acute mania.

In about twenty thousand bodies at the hospital eight were said to have had hydrophobia, and in these at autopsy no gross pathological lesion was found. In three cases recorded as acute mania the microscopic and gross appearances were identical with those in the cases of hydrophobia spoken of.

Dr. J. M. Byron said he had been making experimental investigations with regard to rabies for three years, first under competent direction, and later alone.

Subdural Inoculations not always Fatal.—It had been asserted that subdural inoculations in rabbits was always fatal, but this, he said, was not true; about five or six per cent. of the rabbits recovered.

Immunity not Uniform after Inoculations.—Again, it had been asserted that inoculations by the ascending series, the method of Pasteur, always gave immunity in animals. This was not true, for some, though not many, of the animals died. Further, inoculations made under the skin scarcely ever produced any symptoms at all, never, he thought, rabies. Rabbits paralyzed with subdural inoculations if made to bite other rabbits failed to produce in these rabies.

Dr. Byron further referred to the method of Ferran, who used the strongest virus on man, whereas Pasteur greatly attenuated his. Statistics, he said, showed that about the same number of deaths occurred with as without inoculations by Pasteur's method, and the inference was that inoculations made under the skin in man were useless. For himself, at least, he had never been able to produce laboratory rabies and from this get a virus which would cause rabies in animals when injected under the skin.

Dr. E. D. Fisher had seen two cases of rabies. He thought no intelligent man could deny its existence with the evidence before us. But there might be pseudo-rabies in a hysterical person.

Dr. E. C. Spitzka thought Dr. Ernst could not have read his paper, for in it he had not spoken of experiments which he had made on rabbits; he had experimented on dogs. His object in writing it (it was published in 1886) was to prove that the introduction of a part of the spinal cord of a dog dead forty-eight hours under the dura-mater of a healthy dog would produce meningitis, paralytic symptoms, and death, yet the dog be not affected with rabies. They were then making experiments in his laboratory with cerebral emulsion obtained from a dog nine months ago which had symptoms described as those of rabies. With this emulsion they had inoculaed dogs in series, and they presented symptoms of furious rabies. They had no difficulty in propagating the disease by subdural inoculations, but they had great difficulty in propagating it by subcutaneous inoculations, only a few cases having succeeded and these animals all died of symptoms of so-called dumb rabies while almost without exception those submitted to cerebral inoculations died of symptoms of furious rabies. It might surprise some to learn that the disease which they were inoculating was a true germ disease, the germ being that which had been found in tetanus. About thirty years ago there was a disease among dogs in Iceland, communicated by bite. It affected only dogs, and they all died. On examination typhoid ulcers were found in the intestines, and during life they had frequent stools. The suggestion was made it was probably a form of typhus. Dr. Billings, of Nebraska, had written him that he had isolated a germ different from the one Dr. S. had found, which produced a disease in dogs of fixed duration. From these facts Dr. Spitzka inferred that the question of rabies in dogs would solve itself in this way, that there had heretofore been recorded as rabies complex symptoms common to many different diseases; and that there were a number of intrinsic as well as facultative affections among dogs which presented these symptoms.

Dr. Gray, on being called upon to close the discussion, said he thought there was little to be added except to remark that the diversity, and in some instances, irreconcilable views brought out showed that the discussion of hydrophobia at this time was opportune. The discussion seemed to have proved that there was a disease in the lower animals known by the generic name rabies, which really was not a single disease, but made up of several, probably due to different micro-organisms; second, that that disease occured much more frequently in lower animals than a similar disease known as hydrophobia oc-

curred in the human subject; that while this so-called rabies in animals occurred not very often in this country, it occurred still less frequently in man; that very few physicians had seen a genuine case; that pseudo hydrophobia was by no means very unusual; that there seemed to be a difference of opinion among the speakers whether pseudo-hydrophobia ever produced death; that there was considerable diversity of opinion concerning the exact value of Pasteur's method.

THE NEW YORK ACADEMY OF MEDICINE.

SECTION ON THEORY AND PRACTICE OF MEDICINE.

Stated Meeting, November 18, 1890.

FRANCIS DELAFIELD, M.D., CHAIRMAN.

The Indications for Trephining in Epilepsy.—DR. J. C. MINOR read a paper on this subject. By the administration of drugs, and the careful regulation of diet, exercise, and general hygienic measures, he said, we might hope to cure about one half of all cases of epilepsy, which experience had shown was not an affection that disappears spontaneously. It was among the other half that surgical interference had its field. While, however, all epileptics are subjected to medical treatment, only a small proportion of those unrelieved by such treatment came under the observation of the surgeon. Of these, a majority were rejected, as not appropriate subjects for operation; but of those who were operated on, more than one-half were cured, over one-sixth were relieved, about twenty per cent. died, and about three per cent. were neither better nor worse for the operation. Within the last ten years the mortality had been largely decreased by the application of antiseptics to brain surgery, and the favorable results had increased in equal proportion.

The conclusions reached by Dr. Minor from his study of the subject were as follows: "We have, then, three main indications for trephining in epilepsy that hold good, provided medical treatment or the removal of peripheral irritation by other methods fails to cure or relieve.

"1. In the distinctly traumatic epilepsies following depressed fractures and other lesions of the skull.

"2. In the traumatic epilepsies in which the only visible lesion consists of a scalp wound that is sensitive or tender, and upon which pressure develops either an aura, vertigo, or an epileptic seizure.

"3. In all epilepsies, whether traumatic or not, in which the character and development of the seizures is such as to indicate a definite motor area as the seat of a cortical lesion."

The contraindications, he went on to say, were in brief those that might be applied to cases of such long duration as to lead to marked mental degradation, to cases in which from the first the seizures had been general and sudden, to cases where the general symptoms indicated an extensive cerebral degeneration, and to cases where, in addition to any or all of these conditions, there was nothing in the symptoms or history of the case to indicate a definite or circumscribed lesion of the cortex that could be reached and removed.

As regards the whole subject of trephining in epilepsy, while there was good reason for satisfaction with the results of surgical treatment in these cases, he was quite sure that one of the plainest lessons taught by all this experience was that of the added dangers and difficulties that arose from unnecessary delay in resorting to surgical treatment. Certainly in traumatic epilepsy it was unwise to wait until the increased frequency of the seizures had reduced the patient to an imbecile or idiotic condition before adopting surgical methods of relief. Long before this stage had been reached any competent physician could determine with sufficient accuracy the prognosis of a case of epilepsy under medical treatment; and the proper time to operate began as soon as it became evident that other methods were ineffectual. While it was unwise to advocate undue haste in operating upon these cases, it was equally wrong to defer the operation to such a degree as to materially diminish the chances of recovery.

Surgeons themselves had been led to delay the operation, because the mental symptoms were not very marked, because the seizures were not repeated every day, because the progress of the disease was not rapid; and, finally, after all this had been reversed, the mind impaired, the seizures frequent, and the progress of the disease accelerated, so that the patient's chances of recovery had been greatly diminished by these complications, then the failure of the operation to relieve the condition had contributed to the very prejudices and conservatism that had distinguished the treatment. There could be no question, he thought, that the best results follow the earliest operations, and these results applied not merely to cure or relief, but also affected the question of mortality. It was, therefore, important to bear in mind that the persistence of the primary lesions has a marked influence in determining later and graver symptoms, and that if an operation was needed at all, the sooner it could be done the better for the patient.

Discussion.—DR. ROBERT F. WEIR said that nothing could be added to the rules for surgical interference laid down by Dr. Minor in his paper. The indications thus presented would, he thought, be accepted as judicious by all the principal authorities at the present day, and were in entire accordance with those given by Bergmann in his last lectures. While he had had quite a number of cases himself, he did not feel at all justified in speaking on this subject from his own experience, and he did not think anyone, not even excepting Horsley, had met with a sufficiently large number of cases to enable him to arrive at any positive conclusions from such experience alone. There was one point which was somewhat discouraging, and that was the fact that the mortality from operations still remained so high, ranging from twenty to fifty per cent. It must be remembered, however, that brain surgery was as yet a comparatively new field, and that many of the fatal results occurred under the hands of those who were operating for the first time. Even among the more experienced operators he thought more violence than was necessary was not infrequently employed. But these were errors which would be corrected, at least to some extent, as time went on, and he had no doubt that in the future better results would be reported than had as yet been attained.

DR. ROBERT ABBE, who was to have taken part in the discussion, was unable to be present but sent a note in which he said: "My experience is limited to two trephinings for traumatic and two for idiopathic epilepsy. The cases of idiopathic trouble were victims of degenerating mental state, both being boys of about twelve years. One was often violent after his attacks. I operated less than a year since upon him. The attacks ceased, and his mental state greatly improved. After six months there was a return of his malady, and he required restraint in an asylum. At the operation I opened the dura and found the meninges in a condition of engorgement, and also œdema, suggesting a low grade of inflammation, or at least one of irritation.

"The second case I operated on only three weeks since. There were half a dozen attacks daily. The meninges were also in much the same condition as in the former case. The attacks ceased at once. Primary union of the wound occurred, and the lad was taken to Nova Scotia by his father, who is a physician. No recurrence has yet been reported.

"I feel strongly conservative in regard to the operation for functional epilepsy; but believe it may, and should be tried, with expectation of temporary relief at least, in cases of a severely progressive or degenerating type."

DR. E. D. FISHER said that many of these traumatic cases occurred in children affected with spastic hemiplegia. Although in so many of the cases there was a one-

sided lesion, the attacks for the most part were general in character, not being in any way localized. He had had himself some thirty or forty such cases. When a scar was present it was generally found that no change whatever was produced by pressure on the scar. It was a question, therefore, whether the removal of this scar would be warranted, or would be a good thing to accomplish. In these cases of epilepsy with spastic hemiplegia in children it had been advised to trephine, and reports had been published to the effect that, as a result of the operation, the mental condition had improved and the seizures had disappeared.

There were one or two questions which he said he would like to put to Dr. Minor. In the first place, when a scar was present, but when no irritation apparently resulted from it, and the attacks were general in character, would he advise operation? In the second place, he would like to ask whether trephining, irrespective of any local seizure, would be warranted. This he knew had been done, and if the operation was performed with ordinary care and adequate antiseptic precantions, he did not think it was attended with any special danger. It seemed to him that in these extreme cases we were justified in trying to do something for the relief of the patient.

He then mentioned a case that he had met with where the epilepsy resulted from the kick of a horse. In such a case, he said, we would naturally expect to get good results from operating. Yet, after a few weeks subsequent to the trephining the patient was as bad as ever, and there had been no improvement since. The point of chief interest to him about this whole matter was whether in idiopathic epilepsy without a localized seizure we are warranted in resorting to operative interference. His experience would certainly teach him that in instances where blows or other injuries apparently lie at the bottom of the trouble, the cases are apt to go on to general epilepsy.

Dr. M. P. Jacobi called attention to the suggestiveness of a case reported by Dr W. W. Keen, to which Dr. Minor had referred in his paper. It was as follows: In 1888 an epileptic was sent to Dr. Keen for operation. Being in doubt as to the existence of a depression, he first made an exploratory incision in the scalp. He then lifted a flap and found nothing. The operation was performed under strict antiseptic precautions, and the wound rapidly healed without any rise of temperature. One month later the patient was trephined and the cerebral centre for the left hand and wrist excised. During this operation it became necessary to invade the territory covered by the flap of the exploratory operation. Under this area the dura was noticeably more adherent to the bone than elsewhere. This, said Dr. Minor, taught the important lesson that a marked lesion within the cranium may follow a slight traumatism on the exterior; and it followed that if Keen's exploration of the scalp, so carefully done and so perfectly healed, was followed by a lesion as marked as he described, we might reasonably expect that in many scalp wounds, where no such surgical skill or attention was received, the adhesions of the dura beneath the point of injury might, as Macewen termed it, "anchor the brain to the bone," and thus become a potent factor in the production of epilepsy.

Dr. Fisher said that it had always seemed strange to him that while injuries to the brain frequently caused epilepsy, surgical operations upon it were not followed by this affection. He had never seen epilepsy produced as a result of experimental investigations upon the brains of animals, such as dogs, monkeys, etc.

Dr. Landon Carter Gray said that, like Dr. Weir, he thought that Dr. Minor had presented the subject with good judgment. But still the question arose at the very start, What is epilepsy? We know very well that it was merely a symptom, just as fever and cough were. We might search through the whole field of neurology, however, without being able to find out what it was a symptom of. This was a point that had never as yet been determined. Another question of importance was, Whether, when a reflex, peripheral, or other cause had been removed, the epilepsy would not continue?

In the third place, it had been found that epilepsy was apt to be relieved by any operation upon any part of the body. In fact, any strong impression upon the peripheral nerves would be likely to have this result. This being the case, we were not in a position to judge of the permanency of the cure or relief in the vast majority of cases of operation, because the subsequent histories of the patients were not given for a sufficient length of time following the operation. It was, moreover, a well established fact that many cases of epilepsy would go spontaneously for months and years without a fit. The trouble practically ceased for these long periods. At the time when phimosis was considered of so much importance he had seen the operation for the relief of this condition do quite as much good in epilepsy as had ever been reported from trephining. In the same way, he had seen the removal of a piece of skin from the buttock have a most beneficial effect. When these things were taken into consideration, therefore, it could be seen that there was considerable room for doubt as to the real efficacy of trephining.

Many of the cases of epilepsy dated back from infancy or early childhood, when lesions were produced by parencephalitis or meningitis which it was utterly impossible to remove. In adults some cases were called idiopathic simply because no one had been able to determine what the pathological changes present were. As to traumatic epilepsy, of course, if you could find a cicatrix and remove it, you might perhaps do good; but it was well to bear in mind that just as much good could be accomplished by the operation for phimosis. Even where there had been depression of bone the epileptic habit might continue after this condition was removed. In the brain we could now localize for a certain number of things, such as the extremities, speech, etc., but beyond this all was pure speculation.

In any case of epilepsy, however, it was certainly desirable to know whether the lesion was within reach or not. If the growing doctrine that cortical lesions alone give rise to epilepsy should prove correct, it would be a great point gained for the surgeon, and much might be hoped for the future. There was a certain amount of ground for this opinion, and that subcortical lesions do not produce any loss of consciousness. As he had said before, the histories of the cases of operation were, as a rule, sadly lacking in completeness. He had seen cases of idiopathic epilepsy go for ten years without a fit, and others had reported cases which had no fit for twenty years. This whole question of operation in epilepsy, must, therefore, be regarded as still distinctly *sub judice*, and any advance that might be attempted must be made very carefully and slowly.

Dr. Minor said, in closing the discussion, that the indications for trephining as he had given them had been drawn, not from any special theory as to the nature of epilepsy or its forms, but simply from the records of clinical cases. By judging from clinical experience he had tried to avoid any discussion as to its nature, and he had not consulted tables of statistics (all of which were imperfect) so much as the original reports of cases, as far as he could get at them. As to the matter of a scar, trephining, of course, caused a scar, and several cases were on record where the operation itself had been the cause of a reproduction of epilepsy.

In reply to Dr. Fisher's inquiry as to whether it was justifiable to operate in cases of idiopathic epilepsy when the convulsions were general, and no scar was present, he said that he had trephined in one such case, and the patient was at all events no worse than he had been before. The place selected for the operation was over the fissure of Rolando, and he did not go below the dura mater. This was now over ten years ago. The question of cerebral pressure, due to a disparity between the skull and its con-

tents came up, and the case was supposed to be one of too early ossification of the cranial bones. He thought that he was warranted in trying to relieve the patient by operation; but this was not followed by any result, and he was now in a lunatic asylum. After that he gave up the doctrine of cranial pressure, which certainly did not seem to hold good in the case of the flat-headed Indians, who he had never heard were especially subject to epilepsy. As to the presence of a scar being an indication for trephining, he thought that in his paper he had given about all the data that were warranted by clinical evidence.

Correspondence.

HOW TO GET ALONG IN VIENNA.

(From our Regular Correspondent.)

VIENNA, December 1, 1890.

THE first questions which a student needs to have answered here are, Where am I to live, and from whom obtain instruction? Only those who have had to work out for themselves answers to these interrogatories amid the intricacies and reticences and exasperations of other European medical centres, can appreciate the difficulties involved. In Vienna, however, the matter is made very simple by the Anglo-American Vienna Medical Association, whose office is at 12 Landesgerichts Strasse, near the hospital. This organization is under the supervision of the Rev. Francis Gordon, a young clergyman sent some five years ago by the Free Church of Scotland to take charge of their mission in this city. Very early Mr. Gordon interested himself in the needs of the medical students who form so large a proportion of the English-speaking foreign contingent and of his congregation; and his efforts and those of his helpers finally, in 1889, crystallized in the formation of this association. Its purpose is to give information on all subjects interesting the student, from a course in cerebral localization to the address of a good shoemaker. A committee is appointed from among the students who have been longest in Vienna, and know the ins and outs of work here. These gentlemen are very kind and painstaking in their efforts to help new-comers. The membership fee of the association is one gulden (forty-five cents), and there are no other expenses.

After settling himself and his belongings in some room or *pension*, the stranger will naturally go first to the General Hospital. To one accustomed to the splendid modern structures of New York, Boston, Berlin, or London, the first view of the *Allgemeine Krankenhaus* is not pleasing. Begun in 1784, and added to from time to time as the city's growth demanded, it now consists of a huge, rambling, two-story stucco building, accommodating two thousand patients, and enclosing in its different communicating quadrangles some thirteen courts. The first of these is large, and contains trees and pretty walks, and several of the other courts, though much smaller, are similarly laid out. The whole effect is, however, rather shabby. In the rear of the main hospital stand the Pathological Institute and the Asylum for the Insane—handsome buildings of the modern type.

The lecture-rooms and operating-theatres are old and disappointing. Billroth's and Albert's amphitheatres are cramped, poorly lighted, and ventilation seems not to be even thought of. Hence, after a couple of hours' use by a crowd of Austrian, Polish, and Bohemian students, the air becomes very disagreeable. But one quickly accommodates one's self to these unpleasantnesses, and really forgets them in admiration of the wealth of material exhibited and the skill of the operators.

In the immediate neighborhood of the General Hospital are the long Poliklinik, where instruction is also given all day long and material, numerous corps of teachers. Instruction thus assembled, centralized; and the loss of time and length which one suffers in other cities by long horse-car and omnibus journeys to and from clinics, is prevented.

Probably one of the earliest impressions made upon an American is of the indifference, carelessness, and even cruelty, with which patients are often treated. And this is true of Germany, as well as of Austria. One sees painful operations done without anæsthesia, when the operator is pressed for time; he sees patients stripped, and then covered simply with towels wet in antiseptic solutions, and exposed to deadly chill during long operations in cold amphitheatres—the patient being often required to leave the room afterward wet and naked. He sees women submit to vaginal examinations by a class of nine or ten students, her expressions of suffering being often repressed with great roughness; he sees pregnant women, and women already in labor, chloroformed, and measured, palpated, and examined, inside and out, by classes similarly large, the narcosis terminating with the curiosity of the students. It is often a cause of wonder that so many patients live to establish the reputations of German and Austrian operators, and the question often arises among the American spectators whether hospital patients here are not tougher than with us.

There is also often a lack of delicacy, not to say decency, in the conduct of hospital work. For instance, it takes the stranger from abroad quite aback to see the male patients of the skin and venereal clinics ushered entirely naked into the presence of the professor by a woman; and dressings and applications, even urethral injections, made by the same unblushing female. But these matters soon lose their early novelty, or are swallowed up in the interest which the great opportunities for observation excite.

CARE OF THE PRIVATE INSANE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue of November 29, 1890, you allude in a very brief but forcible manner to the inequalities of the recent New York State law in its application to the care and treatment of the private or paying insane. This class of patients, it would seem, are excluded under the law from admission to your State hospitals, and must seek medical treatment in institutions owned and controlled by private individuals or corporations. To persons of moderate means, who are able and willing to pay a reasonable price for the treatment and maintenance of their afflicted friends, this is manifestly a great hardship, if not a positive injustice. In Alabama, and possibly in most of the States, the same unjust discrimination is made in favor of the indigent insane, and in such of our State hospitals as admit the private or paying insane at all, preference in order of admission is invariably given to the indigent over those who are able to pay their own expenses. The result of this arrangement is that the paying patients are soon crowded out of the State institutions, and are compelled to seek admission in some of the private hospitals.

During my long connection as Superintendent of the Alabama Insane Hospital, I have more than once referred to this matter in my annual reports to the Legislature, and in my last report, just printed, I have made such suggestions and recommendations looking to the removal of the evil complained of, as I am sure will meet with your approval. I submit the following extract from my report:

"**Private or Paying Patients.**—Of the one thousand and fifty-four patients remaining in the hospital at the close of the present fiscal year, forty five are shown in the foregoing table to belong to the private or paying class. The charges for this class of patients vary from twenty to sixty dollars per month, according to the special care and kind of provision they are able and desirous of securing. They occupy rooms in the wards with the other patients, but take their meals at separate tables, and in many cases have special nurses.

"For many reasons it would be better to place these private or paying patients in separate wards, or better still, in a building set apart for their exclusive use. Such a building could easily be erected on our present grounds, and could be made an ornamental as well as a most useful adjunct to our present plant. The building should be of the most approved modern construction, capable of affording such comfort and even luxuries as the most fastidious could desire and were willing to pay for. While the cost of such a building, capable of accommodating one hundred patients, need not exceed a hundred thousand dollars, the receipts for board and medical attention would yield a handsome revenue to the State over and above all expenses. A building of this character could hardly fail to prove a great blessing to such of the citizens of the State as are able and willing to pay a reasonable price for the care and treatment of their insane friends and relatives, and who would prefer to have them as near home as possible. As a pecuniary investment alone, such a building as I have described would well repay the State for the amount expended in its erection.

"I believe that there should be a building exclusively for private or paying patients attached to every public hospital for the insane in the land. Our State institutions need just such an adjunct to make them complete and capable of conferring the greatest benefit upon the people of the State.

"On account of the crowded condition of our wards we have had to decline receiving many paying patients both from our own and other States. Having no suitable accommodations for persons who are able and willing to pay for them, we have found it necessary to direct them to private asylums in other States, where the charges were double and often treble what they are in this hospital. This is a great hardship upon the citizen and tax-payer, who, though able and willing to pay a reasonable amount for the care and treatment of his insane relative, is not able to meet the extravagant demands of the private asylums away from home.

"No institution for the insane, in my judgment, can therefore be considered thoroughly equipped or complete in its arrangements that does not provide for the reasonable wants of all classes of the insane; and I should like to see Alabama take the initiative in a measure so humane, and at the same time so conducive to the comfort and welfare of the better classes of her citizens."

Yours truly,

P. BRYCE, M.D.,
Sup't Alabama Insane Hospital.

TUSCALOOSA, ALA.

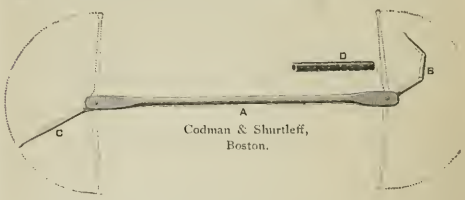
New Instruments.

NEW UTERINE REPOSITOR.

BY R. A. KINGMAN, M.D.,
BOSTON, MASS.

THE uterine repositor is by no means the gynecologist's most useful instrument. Indeed it is comparatively seldom that the need of it is at all recognized, and yet when it is really wanted there is nothing that will satisfactorily take its place. Time and again have I looked over the manufacturers' stocks of instruments for a repositor which seemed to me to meet the requirements of the desired service, but in vain. Emmet's repositor I liked better than any other, but still for certain cases it failed utterly. Jennison's elastic sound appealed strongly to the reason, but it was not strong enough to replace a uterus. Other instruments were all more or less unsatisfactory, so that I was forced either to rest content with what the market so imperfectly supplied or devise an improvement.

The instrument made for me by Messrs. Codman & Shurtleff, after my plans, worked so admirably that success seemed to have been attained, but unfortunately it was found that one of the working parts invariably broke after a short period of usefulness and most careful tempering did not obviate the difficulty. Here the matter rested until, after much experimenting by the firm, the instrument figured below was produced, modelled on the old plan, but introducing a much simpler mechanism.



A straight bar of steel, working in a tube, transmits the power from one rack and pinion to another exactly similar at the uterine end. The two ends being always parallel, as in the case of the sound mentioned above, the external tip serves as a guide to the position of the uterus, and the power being directly transmitted to the uterus without loss or addition, save as it is slightly affected by the friction of the parts, one's operating hand receives prompt notice of any adhesion or resistance and there can be no excuse for using undue violence. The instrument is reversible, the hard rubber tube D transforming the jointed tip into a rigid handle if desired.

I have found this repositor of great value for replacing and holding in approximately correct position the dislocated uterus during firm packing, the progress toward a complete reposition being much more rapid than under other circumstances. The fact that the instrument is strong, not liable to deteriorate or get out of order, and is easily cleaned, is strongly in its favor.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 21 to December 27, 1890.

RAYMOND, THOMAS M., First Lieutenant and Assistant Surgeon. Having been ordered to temporary duty at Vancouver Barracks, Wash., by the Commanding General, Department of the Columbia, is assigned to duty at that post, and relieved from further duty at Fort Sherman, Idaho. S. O. 294, A. G. O., Washington, D. C., December 17, 1890.

TAYLOR, MARCUS E., Captain and Assistant Surgeon. Paragraph 17, Special Orders No. 287, December 9, 1890, is so amended as to direct him to report to the commanding officer at Vancouver Barracks, Wash., for duty as post surgeon, relieving Colonel Bernard D. Irwin, Surgeon, of that duty. S. O. 274, A. G. O., Washington, D. C., December 17, 1890.

EBERT, RUDOLPH G., Captain and Assistant Surgeon. Will be relieved from duty at Vancouver Barracks, Wash., upon the arrival of Captain Taylor, and will then proceed to Fort Huachuca, Ariz. Ter., and report in person to the commanding officer of that post for duty. S. O., 274, A. G. O., Washington, D. C., December 17, 1890.

COWDREY, STEVENS G., Major and Surgeon. By direction of the Secretary of War, the extension of leave of absence granted in Special Orders No. 263, November 10, 1890, from this office, is further extended on account of sickness. S. O. 293, par. 4, A. G. O ington, D. C., December 16, 1890.

IVES, FRANCIS J., Captain and Assistant Surgeon, now on leave of absence. By direction of the Secretary of War, will proceed to Rapid City, S. D., and report in per-

son to Colonel Eugene A. Carr, Sixth Cavalry, for duty with troops in the field, relieving First Lieutenant William B. Banister, Assistant Surgeon, and reporting, also by letter, to the Commanding General, Department of Dakota. S. O. 289, par. 18, A. G. O., Washington, D. C., December 11, 1890.

STEPHENSON, WILLIAM, Captain and Assistant Surgeon. Granted leave of absence for fourteen days, to take effect on or about December 29, 1890. S. O. 291, par. 18, A. G. O., Washington, D. C., December 13, 1890.

REED, WALTER, Captain and Assistant Surgeon, now on duty at Baltimore, Md. By direction of the Secretary of War, will report in person, without delay, to the commanding officer at Fort Keogh, Mont., for temporary duty at that station, and by letter to the Commanding General, Department of Dakota. S. O. 291, Headquarters of the Army, A. G. O., Washington, D. C., December 13, 1890.

OWEN, WILLIAM O., JR., Captain and Assistant Surgeon, now on leave of absence. By direction of the Secretary of War, will report in person, without delay, to Colonel Eugene A. Carr, Sixth Cavalry, at Rapid City, S. D., for duty with troops in the field, and by letter to the Commanding General, Department of Dakota. S. O. 291, par. 17, A. G. O., Washington, D. C., December 13, 1890.

SMART, CHARLES, Major and Surgeon. By direction of the Secretary of War, detailed as a delegate to represent the Medical Department of the Army at the annual meeting of the American Public Health Association, to be held at Charleston, S. C., December 16 to 19, 1890. He will proceed to Charleston accordingly, and upon the final adjournment of the Association return to his station in this city. S. O. 290, par. 2, A. G. O., Washington, D. C., December 12, 1890.

WALKER, FREEMAN V., First Lieutenant and Assistant Surgeon. By direction of the Secretary of War, the leave of absence granted in Special Orders No. 85, Department of the Platte, November 11, 1890, is extended one month. S. O. 298, par. 9, A. G. O., Washington, D. C., December 22, 1890.

COCHRAN, JOHN J., Captain and Assistant Surgeon. By direction of the Secretary of War, granted leave of absence for six months on surgeon's certificate of disability, with permission to leave the Department of Texas. S. O. 298, par. 2, A. G. O., Washington, D. C., December 22, 1890.

GIBSON, ROBERT J., Captain and Assistant Surgeon, now on leave of absence. By direction of the Secretary of War, will report in person, without delay, to the commanding officer, Fort Meade, S. D., for duty with the Seventeenth Infantry, in the field, reporting by letter to the Commanding General, Department of Dakota. S. O. 297, par. 6, A. G. O., Washington, D. C., December 20, 1890.

Official List of Changes in the Medical Corps of the United States Navy for the week ending December 20, 1890.

EVANS, SHELDON G., Assistant Surgeon. Ordered to Naval Academy, Annapolis, Md.

DECKER, CORBIN J., Passed Assistant Surgeon. Detached from Naval Academy, and ordered to Naval Hospital, Philadelphia, Pa.

A New Diuretic.—Dr. Gram, of Copenhagen, has lately introduced a new drug known as diuretin. It is made by combining theobromin in such a way as to make it exceedingly soluble, of rapid absorption, and very pleasant to take. It has been tested clinically in Strassburg; is found to act directly on the kidneys without any action on the heart or nervous system, such as we have in digitalis and caffeine.—*Dietetic Gazette.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 20, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	9	5
Scarlet fever	108	11
Cerebro-spinal meningitis	1	1
Measles	253	19
Diphtheria	94	31
Small-pox	0	0
Varicella	8	0
Pertussis	7	7
Croup	1	0

A Correction.—In the issue of the MEDICAL RECORD for November 22, 1890, Dr. Woodward is mentioned as the author of an article in the *Journal of the Military Service Institution* concerning the United States Army Medical Department. A correspondent calls attention to a typographical error in that the author of the article in question was Lieutenant-Colonel A. A. Woodhull of the Medical Department United States Army.

In Memory of Richard J. Levis.—At a special meeting of the Faculty of the Philadelphia Polyclinic and College for Graduates in Medicine the following preamble and resolutions were unanimously adopted:

"*Whereas*, The Divine Ruler of the Universe has seen fit to remove from among us Dr. Richard J. Levis, our friend and colleague; therefore, be it

"*Resolved*, That not only in the Emeritus Professor of Surgery of the Philadelphia Polyclinic, but the whole medical profession have lost an honored and faithful co-laborer; and the community have cause to mourn a skilful and learned physician, an honest and sympathizing friend.

"*Resolved*, That by his kindness of manner, by the thoughtful interest which he always manifested in the younger members of the profession, by his encouragement, his earnestness, and his example he had endeared himself to all, and that we fitly honor and cherish his memory we must emulate his zeal and vie with each other in carrying forward the great work in which he was so ardently engaged.

"*Resolved*, That we tender to his family in this sad hour of affliction our heartfelt sympathy.

"*Resolved*, That these resolutions be handed to the family of our beloved colleague and to the medical journals.

"THOMAS J. MAYS, *President.*
"S. SOLIS COHEN, *Secretary.*"

Chestnuts for Ivy-poisoning.—Dr. S. B. Straley (*Times and Register*) has found that a strong decoction of chestnut leaves (*castanea fagus*) promptly cures ivy-poisoning. Dr. J. Aban Kite cotemporaneously announces (*Medical News*) that lotio niger is also a specific.

Suicide among School Children in Prussia.—Recently published statistics show that there is more "overpressure" among school children in Prussia than in England—or, at any rate, that it leads to more tragic results. In the six years 1883-88 there were 289 cases of suicide among school children in Prussia, 240 of them having been boys and 49 girls. The cases are apportioned among the different years as follows: In 1883 there were 58 suicides; in 1884, 41; in 1885, 40; in 1886, 44; in 1887, 50; and in 1888, 56. In 86, or 29.8 per cent. of the cases, the motive of the deed is unknown; but in 80 the cases, were "fear of punishment;" in 19, "disappointed ambition;" in 16, "fear of examination;" and in 28, "insanity and melancholia;" 5 of the suicides are attributed to "love," and 7 are believed to have been half unintentional.

Calculi in Dermoid of the Bladder.—A woman, aged fifty-seven, under the care of Dr. Feleki, of Buda-Pesth, complained to him that she had suffered for eight years from distressing dysuria. Sometimes she was forced to rise twenty times in the night, and could only pass one drop on each occasion, and always with severe pain. This condition lasted for several weeks at a time, and ended, temporarily, in the passage of a smooth, hard body, at first taken for a renal calculus. At length the patient owned a large collection of small stones, not including innumerable minute fragments passed and lost during micturition. She declared that her urine was free from sediment, and not turbid. The bladder was explored, and a mass of calculi discovered and broken up and removed by litholapaxy. About two hundred pieces of calculus were thus taken away. Each entire calculus had a nucleus, or rather an axis, consisting of a fair hair (human, as was proved), over an inch in length; some of the hairs were connected with three or four small stones, so as to form bead-like structures. Many such rows of beads had been passed voluntarily. The calculi were phosphatic, ranging from the size of a melon-seed to that of an almond. There was no evidence of the artificial introduction of hair into the bladder. The pelvic viscera were carefully searched, and no evidence of dermoid tumor in connection with the pelvic organs outside the bladder could be detected. This fact, coupled with the presence of the curious rows of calculi strung on single hairs, indicated that the original disease was trichiasis vesicæ, an "open dermoid" or growth of hair direct from the vesical mucous membrane. No other dermoid structure, besides hair, was at any time voided or extracted from the patient's bladder.—*British Medical Journal.*

The Fever in Scarlatina.—Dr. Reimer, basing his statements upon a large number of thermometric tracings, divides scarlatina into the following forms:

	Per cent. of Mortality.
1. Simple or uncomplicated scarlatina.	
a. Mild	0.0
b. Severe	83.76
2. Complicated.	
a. Short, mild	2.08
b. Short, severe	6.94
c. Long, benign	5.66
d. Malignant	39.34
e. Prolonged, benign	26.47
Malignant	79.99
3. Scarlatina following other diseases	81.96
4. Scarlatina followed by other diseases	44.32

In the treatment of three thousand four hundred and sixty cases of the disease, nine hundred and seventy-eight were subjected to hydrotherapy, which was used with the idea of reducing the temperature in the following forms: 1, Cold compresses; 2, cold envelopment; 3, cold with dry friction; 4, cold with affusions of water in the empty tub; 5, cold with affusions in a half-bath progressively cooled; 6, short or long tepid baths; 7, full baths gradually cooled; 8, cold half and full baths with friction. Cold compresses upon the head, thorax, and abdomen were frequently used, except in cases in which the restlessness of the patient was so great as to make its use too difficult. Their action was favorable upon the heart, but they did not lower the temperature to any great extent. Cold envelopment was used, especially in nervous, anæmic, or rachitic children. There was a favorable action upon the heart, but hardly any effect upon the temperature. Cold envelopment combined with dry friction was used in cases in which it was desired to produce cutaneous revulsion and excite the nervous system. Under their influence the respiratory movements became more regular, but the temperature showed no change. Cold envelopment combined with affusions of water in the empty tub, the temperature of the water being 54 to 57° F., were tried in cases of cyanosis, stupor, and collapse. This treatment, used with all proper precautions, generally gave good results, but there was no effect on the temperature. Results quite as favorable were obtained with cold envelopment followed by affusions in a gradually cooled bath. In some of these cases the phenomena of collapse were notably aggravated, hence this method calls for unusual precaution in its use. The effect of prolonged tepid baths was bad. The temperature was unintluenced and a general weakness resulted, which in some cases was of a threatening character. The same was true in all cases in which a gradually cooled bath was used. Such baths have a sedative effect in typhoid fever, but in scarlatina their effect is pernicious. The efficiency of full cold baths in scarlatina was undoubted if they were used methodically and with proper precautions. The patient is plunged into a tub half-filled with water at a temperature of 54° to 57° F. After removing him from the water he must be rubbed briskly and then wrapped in a woollen blanket. In such cases the temperature will frequently drop several degrees. The patients seem much relieved by such bathing, and will desire its repetition. It is impossible to give general rules for the use of hydrotherapy in scarlatina; the indications will vary with the progress of the disease. With regard to the treatment of the disease by the use of antithermic remedies internally, the author did not obtain favorable results with quinine, sulphate of soda, kairine, thallin, etc. On the other hand, the antithermic action of antipyrin never failed, but its use should be attended with the greatest care on account of the danger of collapse.—*Archives of Pædiatrics.*

Absence of Powder marks no Evidence against Suicide.—Dr. Meigs Case writes that in two recent cases of suicide of prominent men, both of whom had evidently shot themselves in the head, there were no powder-marks visible on the skin. In another case in New Jersey there was much said at the coroner's investigation about the absence of the usual areola of unexploded powder. The improvements made of late in the manufacture of powder have apparently destroyed the value of much of the evidence hitherto regarded as indubitable.

Permanganate of Potassium as an Application to the Bites of Poisonous Insects.—Dr. S. F. Dupon, of Fort Havack, Ga., writes that he has employed permanganate of potassium with striking success as an antidote to the venom of poisonous insects and fish. A solution in glycerine (℥ ij.–℥ j.) is applied externally, and has given speedy and positive results in his hands. He mentions the case of a boy, who had been stung by a spider on the thigh, and whom he found in great agony with thigh greatly swollen. Within an hour after the application of this solution the pain had disappeared and the swelling was much reduced. Another case was that of a negro boy who had been stung by a "stingaree" (a salt-water fish), and who was in convulsions when found. In four hours after the application this boy had entirely recovered and returned to his fishing. Dr. Dupon has also found saleratus useful in similar cases, and recommends its use when the permanganate is not at hand. It should be made up into a paste with water, and applied to the bitten part.

Simultaneous Dislocation of both Shoulder-joints.—Mr. T. W. J. Allen reports the following case in *The Lancet* of August 9, 1890: "A young man, aged twenty-four, works on the Fish Dock driving a cart and packing fish. Within the last four years he has from different causes dislocated the right shoulder four times and the left shoulder three times, and on each occasion came under my observation. On one occasion Mr. Allen was called in to see him and found him suffering from a subcoracoid dislocation of both joints. He said that on getting hurriedly out of bed to assist an invalid brother he turned faint and fell, and upon recovering his senses found both his shoulders 'out.' The deformity was easily reduced by the heel in each axilla in the usual way."

GASTRO-ENTEROSTOMY RATHER THAN RESECTION FOR CANCER OF THE PYLORUS, WITH A CASE OF GASTRO-ENTEROSTOMY.[1]

BY ROBERT F. WEIR, M.D.,

SURGEON TO THE NEW YORK HOSPITAL, PROFESSOR OF CLINICAL SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

GENTLEMEN: I beg to present for your inspection to-night a patient, aged forty-one, upon whom I performed, about one year ago, a gastro-enterostomy for the relief of a supposed fibrous stricture of the pylorus. At that time the symptoms had lasted two years, and his weight had been reduced to one hundred and four pounds. The operation was done by means of Abbe's catgut rings. The details of his symptoms and of the various steps of the operation were given at a clinical lecture at the time of operation, and have already been published elsewhere.[2]

The progress of the case was in every way satisfactory. The patient made a rapid recovery and has continued in fairly good health, increasing in weight, to the present time, some sixteen pounds. During the past two months, however, some moderate occurrence of the symptom of vomiting has taken place. Now, this return of one of his old troubles may perhaps be explained in one of several ways. It will be noticed that the cicatrix of the wound in the abdominal parieties has yielded somewhat, and allows a hernial protrusion upon coughing, or other expulsive effort, and this, too, in spite of the great care taken in sewing up the wound in different layers, *i.e.*, fascia to fascia, muscle to muscle, and so on—a procedure which is generally sufficient to secure a tight cicatrix.

It was at first supposed that the traction of the protruding intestine through the abdominal defect might be sufficient to increase the angle, temporarily at least, at which the intestine was attached to the lower wall of the stomach, and so to produce more or less obstruction at the new opening, or to force biliary secretion into the stomach; but on carefully applying a truss, or pad, no special improvement followed, nor were any biliary salts to be detected in the stomach by chemical reagents.

The next important question to decide was to determine whether the plan followed at the time of the operation was not at fault. At that time, after the abdominal cavity had been opened, the hand was carried down to the vertebral column, feeling for the head of the pancreas, and then passed to the left of the median line, falling upon a loop of intestine which was seized and traction made upon it. Had this met with resistance, it would have indicated, of course, that one was pulling upon a fixed point, the duodenum; but this was not the case, and after one or two repetitions of this effort to grasp in this way the upper end of the jejunum, instead of further persistence in this direction, the suggestion of Lücke, not to prolong the operative time in the search, was followed, and a loop of small intestine situated nearest to the stomach was caught hold of, brought out, incised, and sewn to the wall of the stomach. This advice of not unduly searching for the upper end of the jejunum, while in a great measure a wise one, and supported by the authority of the Strassburg surgeons, who had a succession of successful gastro-enterostomies, as well as by surgeons of eminence elsewhere, has a disadvantage which, to my mind, is quite an important one.

Lauenstein, for instance, in a case where he followed this procedure, was surprised to find his patient rapidly emaciating, and the stools daily showing masses of undigested food. At the autopsy, which took place at the end of eleven days, it was ascertained that the opening in the small intestine was situated within a short distance (fifteen inches) of the ileo-cæcal valve. Herbert Page, of London, also had a somewhat similar case—the intestinal opening being nine inches from the cæcum—the patient living seventy-three days after the operation.

Close observation of the fecal passages of my patient shows completely digested food, and the fact of his continued improvement in flesh is in itself proof that we have not opened too low down upon the intestinal tract and deprived him of an undue amount of nourishing intestinal area.

Another possibility existed, and it was this: that the opening made at the operation might have contracted to such a degree as to no longer permit food to freely pass from the stomach to the intestine. This is not a fanciful idea. Dr. Abbe had been struck by the fact of such openings contracting to a marked degree in one of his own cases of intestinal anastomosis. Czerny, who at one time contented himself with openings in gastro-enterostomy of but 3 ctm. long, advises now to make such larger, as had been previously suggested by Lücke; since in one case of his own, where an autopsy was made five and a half months after the operation, it was found that the artificial opening had been reduced in diameter to 9 mm., less than half a centimetre; and Stanfield also reports a case where, after the use of Senn's plates, with a one-inch incision in the stomach and bowel, at the autopsy, four months later, the opening was found to have entirely closed, though the silk stitches that held the plates together were found in situ. Ransohoff, also, in using Senn's plates with a one-inch opening, found at the autopsy, one month later, that the opening was smaller than the pylorus. Not only in my case was this improbable because the opening made at the time of operation with Abbe's rings measured two inches (or 5 ctm.), but by the two following tests this possibility was settled not to exist.

I may first say that the matters vomited by this man consisted largely of mucus free from biliary matters, which Lauenstein says when present does not, as some have stated, excite emesis; basing his remarks on several cases of gastro-enterostomy where these were found in the stomach continuously. The vomiting occurs about once a day. On, however, administering to him food the débris of which can be traced for a considerable time, such as highly salted corned beef, none such has been found in the matters ejected. This test has been repeated in a variety of ways. His food is therefore digested and presumably passed into the intestine.

More satisfactory was the second test. Air was pumped in through a rubber tube into the stomach. By this procedure this viscus could be only very moderately dilated, and when a stethoscope was applied to the region of the lower border of the stomach, gurgling of air into the adjoining intestine could be distinctly heard, and traced for several inches down the intestine. We therefore knew that he had no such impending danger as a

[1] Presented at the Surgical Section of the New York Academy of Medicine, December 8, 1890.

[2] Medical News, December 14, 1889.

too narrow opening into the jejunum. To all these considerations in explanation of his vomiting may be added the final fact that his condition has been much improved since his stomach has been daily washed out with plain or slightly alkaline water. In other words, that his stomach, which, prior to the operation, had been distended to such a degree as to hold ten pints of water, had by the long action of his stenosed pylorus become so stretched and atonied, that, like the same condition in the bladder, it does not regain its tone, its secretions are impaired, and no doubt it is baggy, and possibly, from sagging, holds secretions which, in a more active organ, would run out through the artificial opening, but now are retained till the act of vomiting relieves it of the accumulated contents. The lavage of the stomach and enforced rest on the right side is now rapidly lengthening out the intervals of vomiting. It is not thought advisable to attempt at present to close the weakened spot in the abdominal wall, unless it should be distinctly proven to be a cause of his existing difficulties, as it allows of increased facility of exploration for tumor, no evidence of which has yet presented itself to the touch, though recently hydrochloric acid is wanting in the gastric secretions.

In the remarks made at the time of the operation the end mainly aimed at was to present the advantages of gastro-enterostomy in pyloric stenosis over Loreta's operation of stretching the pylorus, and attention was called to the greater mortality of Loreta's operation—some forty per cent.—and to the disposition to recontraction which takes place, the originator himself having encountered this three times, in two of which cases a second operation was resorted to. It was from a consideration of these facts that the operation of gastro-enterostomy was advised and performed in this particular instance. At that time. I presented a list of nine gastro-enterostomies in non-malignant stenosis, with but eleven per cent. of mortality; and the operations, moreover, which made up this list were done according to the old method, and required a period of from one to two and a half hours for their performance. Since, however, the improved method introduced by Senn of using decalcified bone plates, to secure with the least amount of suturing the apposed peritoneal surfaces, when an opening is made between two portions of an intestine, or between the stomach and intestine, the mortality has been markedly lessened.

Instead of being, for instance, forty-two per cent. for cancer, as given by Rockwitz, the mortality was, by the approximation method, but one case in the eleven that I was able to collect up to that time. Since then the total number has risen to twenty-six cases, with five deaths—a mortality of nineteen per cent., or, leaving out McBurney's, nearly moribund when operated on, and Polk's fatal, from a remediable fault in the technique, there would be the satisfactory reduction in the death rate to twelve per cent. This is for cancer, remember—for non malignant stenosis, even by the old method of operation, the mortality was but eleven per cent. The decision I arrived at in my patient's case, stated concisely, was based on a mortality of eleven or twelve per cent. for a gastro-enterostomy, against a mortality of twenty-five to forty per cent. in Loreta's operation.[1]

To-night, in taking part in a discussion on the subject of pylorectomy, I venture to apply these very favorable statistics afforded by gastro-enterostomy for cancer, by intestinal anastomosis, in contrast to another operation, to wit, resection of the pylorus. This latter operation, introduced by Billroth, has been performed a sufficient number of times by competent surgeons for us to nearly make up our minds as to its actual value; and, I think, anyone who goes over the cases that are presented in the various journals, or, what is much better and fairer to the operation, should examine the statistics of those who are recognized—by previous large experience in general surgery, or in this particular operation—to be masters of the technique, it will be found that the mortality is yet so fearful and the prolongation of life so little, in the few that are saved, that it, as an operation, might be relegated soon to those which may be considered merely as experimental. I have long felt that it was an operation which had not much probability of a future. I do not yet see anything to change this view. In collecting, for instance, the cases presented by Billroth himself, 28 in number; by Anger, 6 cases; by Lauenstein, 12 cases; by Lücke, 24 cases, and by Czerny, 10 cases—one gets a sufficient number of well-managed operations to judge of the result. Footing up the total, we have 80 cases in all, and 41 deaths. Of those that survived, according to Billroth's report, 13 in number, 6 died within six months of the operation; 2 between the first and second year; 2 between the second and third year, and only 1 lived beyond three years. This last case may be considered to be a cure—the only one, save one other, recorded so far. Czerny reports that his three recoveries lived between five months and two years; and so on with the other surgeons quoted.

Now, the cases operated upon for cancer by gastro-enterostomy, in conditions which are admittedly more severe than those treated by a pyloric resection (for they were mostly cases that were not considered fitted for pylorectomy), lived according to Billroth, in 14 cases from one year to fourteen months; and according to Navaro, in 16 cases the duration of life extended from three to nineteen months. Now add to a continuance of life of nearly the same amount by gastro-enterostomy the fact of an increased saving of life by this operation, and the argument against a pylorectomy becomes very strong.

In the 96 cases of gastro-enterostomy that I have collected from the same observers there were only 39 deaths, and all these were done by the old method of operation, that is to say, a mortality of forty per cent. This percentage is carried down, as just stated, by the safer and quicker method of the approximation plates or rings, to twelve per cent., viz., 3 deaths in 24 cases. In other words, a twelve per cent. mortality by gastro-enterostomy, in the hands of surgeons of limited experience in the use of the improved method, can be placed against fifty-one per cent. of mortality from pylorectomy for cancer, by surgeons fully masters of the operation. Could, as it should be, a gastro-enterostomy be employed earlier in the disease, the death-rate would naturally be less than this even.

One further remark is this—that of the 22 deaths out of Billroth's 41 cases of pylorectomy for fibrous stenosis *and* cancer there were 16 deaths from the stitches giving way. This is due mainly to the inability in this region to always confront two serous surfaces together by suturing—the defect being of course in the duodenal end. The operation of resection, if such is practised, will, in the judgment I rendered last year, be better accomplished by a predetermined independent closure of the duodenal and stomach openings, by turning them in and suturing the same, and then resorting to a gastro-enterostomy in a *separate* part of the stomach. This can be done in less time than the ordinary resection, and this method of reunion of the divided ends proved successful in Tuholske's and Bull's cases.

In conclusion, reference has been made to the use of Senn's plates and Abbe's catgut rings, as being the most serviceable of all the various contrivances that have been suggested for keeping apposed the peritoneal surfaces and for expediting this operation, which in experienced hands should be accomplished in from thirty to forty minutes. Each of these appliances has its faults. This has already been alluded to in respect to Senn's plates: the opening is too small. This must be made very much longer, which is a matter not easily accomplished. They are not very readily made at home, and one must depend for this enlarged pattern upon the slow methods of our suppliers of surgical appliances. Abbe's rings can be quickly made of any size, but unless manufactured strictly in ac-

[1] See article quoted, Medical News, December 14, 1889.

cordance with the instructions of their suggestor [1] they may prove faulty to a serious degree.

In a case reported by Dr. William M. Polk, where gastro-enterostomy by Abbe's rings was resorted to, with a fatal issue, it was found on the autopsy that the rings, which had been made of catgut, had been twisted in a figure of **8**, and hence had pulled upon the stitches in such a manner as to cause a marked solution of continuity, and a disastrous leakage. Dr. Abbe guards against the error made in the case just alluded to by expressly stating that the catgut should be so placed in the immersion fluid that it can be freely untwisted, and that only such untwisted catgut should be used in the formation of these approximation rings. This, I understand, was not done in the above-described case. Furthermore, after being made, he says that they should be held until required for use—the longer, the better—between two plates of glass and kept immersed in alcohol. I have tested a number of rings of some date of Dr. Abbe's manufacture by throwing them into water, and found that this twist did not occur.[2] But the suturing in this case was carried only at each end through the walls of the stomach and intestine, instead of in six places as Dr. Abbe suggests. So far, I am still firm in my belief in the excellence of Abbe's rings. The plates of decalcified bone of extra length are unwieldy and too wide for the small intestine.

ON THREE CASES OF PYLORECTOMY WITH GASTRO-ENTEROSTOMY.[3]

By WILLIAM T. BULL, M.D.,

PROFESSOR OF SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK; SURGEON TO THE NEW YORK HOSPITAL.

It seems strange that in this country, where so much good work has been done, both experimentally and practically, in the surgery of the abdomen, so few efforts have been made for the cure of cancer of the pylorus. American surgeons have recorded more cases of recovery from abdominal section for traumatisms than those of any other country, and the principles and technique of intestinal anastomosis have been worked out with great enthusiasm and applied with good results. Up to the present moment we seem to preserve the same attitude toward resection of the pylorus for cancer that was taken by an admirable writer in the *Medical News* of November 23, 1883, who, after reviewing the situation of the operation up to that date, writes: "Although the technique of the operation is almost perfect, the obstacles to the proper insertion of the sutures and to fashioning the wound of the stomach to that of the duodenum are not easily surmounted by the surgeon who has to deal with his first case. If to these difficulties be added the adhesion met with in so large a proportion of cases, along with the shock which, of necessity, must attend so prolonged an operation, it is obvious that pylorectomy must be excluded from general surgery. Indeed, in view of its great mortality, of recurrence in one half of the cases that had survived long enough to determine this point, and of the doubts as to the final termination of the remaining cases which were living at the last reports, it is questionable whether it should be repeated by those who have had the most experience with it."

This view, which is in my opinion quite rational in consideration of the state of our knowledge seven years ago, may account for the lack of interest in this operation. But it is a gratifying reflection to note that much progress has been made in a few years, that the "almost perfect technique" has been bettered, the statistics have improved, and that pathological facts have been brought to light which make operative possibilities more encouraging. So far as mortality is concerned, the death-rate of seventy five per cent., noted in above sixty cases by different operators up to 1883, has been, in the hands of one surgeon, Billroth,[1] reduced to fifty-seven per cent. (15 deaths in 26 cases), and still further to fifty-three per cent. (22 deaths in 41 cases),[2] and Kocher [3] has just reported three successive cases of recovery. Of 11 of Billroth's successful cases the duration of life before fatal recurrence occurred varied from four months to five and one-fourth years, and was, on the average, seventeen months. One of Kocher's cases lived three years and died, free from recurrence, of pyloric stenosis caused by peritoneal adhesions; another, aged sixty-three, was living and in good health at the end of two years, while the third fell a victim to stenosis of the pylorus and recurrence of the cancer at the end of six months. This improvement has been gained by the use of the unaided suture for the union of the stomach and duodenal ends after resection. Neither the bone plates of Senn nor any of their substitutes have been employed. But Rawdon,[4] of Liverpool, has performed his first case of resection with their aid and obtained a prompt recovery, and Jessett,[5] of London, and a number of American surgeons have demonstrated the advantages of "approximation plates" in gastro-enterostomy and circular enterorrhaphy which present similar technical difficulties with union after resection of the pylorus.

A new future seems possible for pylorectomy with this improved method, and I share the conviction of Matas,[6] who, in a thorough review on "The Present Status of the Operations of Intestinal Anastomosis," writes: "The operation of pylorectomy has been much simplified by the introduction of Senn's method, and, judging from the present outlook, the mortality of this most formidable procedure will be much diminished in the future." Another departure from the typical resection is the combination of pylorectomy with gastro-enterostomy, the cut edges of the stomach and duodenum being shut off so as to form a blind cul-de-sac, and an anastomosis made between the stomach and jejunum. This procedure, first adopted by Billroth after the removal of an unusually large tumor of the pylorus, and suggested to me by my colleague, Dr. R. F. Weir, has been followed in the three cases I am about to report and by Dr. Tuholske,[7] of St. Louis. Billroth, however, attached the loop of jejunum to the lower part of the wound in the stomach, a much more complicated procedure than the one I adopted—closing the stomach entirely and making by means of Abbe's catgut rings an anastomosis through a new opening in the anterior wall near the greater curvature. Tuholske's case died of shock, Billroth's from peritonitis due to faulty suturing. My first case recovered, the other two died from defects in technique. It is obvious that further experience is needed to estimate the value of this procedure, which is, however, not to be lost sight of, inasmuch as it may be unavoidable in the presence of any large growth, or, as has been pointed out by Mr. Jessett, in case the first part of the duodenum is but partly covered by peritoneum and thereby unsuited for satisfactory union with the stomach.

CASE I. *Pylorectomy and Gastro-enterostomy; Carcinoma of Pylorus and Greater Curvature of the Stomach; Recovery.*—Fanny T——, aged twenty-seven, born in Ireland, widow, was admitted to the New York Hospital March 4, 1890. Her general health had been perfectly good until April, 1889, when she began to have nausea and vomiting, with irregularity of bowels. She had never

[1] Medical News, June 1, 1889.

[2] In the discussion that followed Dr. Kammerer narrated an instance in which a catgut ring, prepared fully in accordance with Dr. Abbe's directions, twisted in a similar figure of **8** shape, and thus separated the line of suturing. An undecalcified bone plate was used in one case on the gastric side of the opening. It was found unchanged in the stomach at the autopsy, seven weeks later.

[7] Medical News, vol. lvi., p. 503.

been pregnant. The gastric symptoms continued, gradually increasing in severity. The vomitus always consisted of ingesta, and never contained blood. The vomiting at first occurred just before eating, later soon after eating. Seven months ago symptoms abated temporarily and for two months she was apparently improving. Five months ago nausea and vomiting became more frequent and she began to have severe lancinating pain in the epigastrium. Four months ago she first noticed a small hard "lump" a little to the left of the umbilicus, which she could move with the hand. She also noticed that it changed with change of position. The tumor has gradually increased in size and has become more movable. There has been a gradual diminution of flesh and strength. She has lost thirty pounds during the last four months and has become pale and weak.

On admission to the hospital she was markedly anæmic and emaciated. Heart and lungs were found normal. In the recumbent position, occupying the central portion of the abdomen was a tumor irregularly quadrilateral in outline, four and three-fourths inches in transverse and two and one-half inches in vertical diameter. The upper, lower, and left borders were notched, while the right was distinctly concave. When displaced upward the tumor tended to move toward the left and could be felt almost in the normal position of the left kidney on bimanual palpation. It could be moved to the right as far as a line going through the anterior superior spine of the ilium, upward to a point two inches below the ensiform cartilage, and downward to a point three inches above the symphysis pubes. Manipulation was only painful when carried to an extreme, but was followed by an increase in nausea and vomiting. The kidney could not be felt on either side although the abdominal walls were thin and very lax.

The tumor was at first supposed to be a malignant growth of stomach, intestine, or kidney. After a consultation with my colleagues, Dr. Stimson and Dr. Ball, an exploratory median laparotomy was performed on March 8th. The tumor was found to be a new growth, evidently carcinomatous in character, occupying the pylorus and greater curvature of the stomach, and involving more of the posterior than anterior wall. The surface of the tumor was smooth, covered with peritoneum, and not unlike a kidney in outline and appearance. The kidneys were felt in normal position on both sides. The abdominal wound was quickly closed. A speedy and uninterrupted recovery ensued, and the patient left the hospital at the end of three weeks. The nature of the tumor was explained to the patient and a second operation for its removal proposed, its attendant risks being fully explained. On April 3, 1890, she returned, desirous of having the operation performed. She was put upon liquid diet every two hours and kept quiet in bed up to the day of operation, one week later.

April 10th.—In the interval she had some nausea and vomiting, and moderate pain. The vomited matter was carefully tested for free hydrochloric acid, but no trace found.

Urine, sp. gr. 1.008, alkaline, amber in color, contained a trace of albumin, and a few leucocytes; urea normal in quantity. On the day previous to the operation the bowels were thoroughly moved by cathartics, and on the morning of the operation an enema of soap-and-water was given. Liquid food was kept up until four hours before the operation, and brandy was given by the mouth after the food was stopped. Just before the operation an enema of brandy, ℥ j.; strong black coffee, ℥ j.; hot water, ℥ ij. was given.

Operation April 10, 1890, at 3 P.M., under ether. As soon as she was anæsthetized the stomach was thoroughly washed out with warm Thiersch's solution. I made a median incision six inches long, three inches above and three inches below the umbilicus. A portion of the gastro-hepatic omentum was found adherent to the parietal peritoneum; this was torn off and tied with silk ligature. There were no other adhesions, no other cancerous deposits. One hour was spent in separating the omenta from the portion of the stomach to be removed. This was done by means of a double row of silk "chain ligatures," introduced with a curved needle, each embracing only a small portion of tissue. The omentum was cut between the two lines of ligatures; several glands were noticed in the great omentum close to the greater curvature, and the line of ligatures placed beyond these and an inch or more from the colon.

An oblique circular incision was then made well beyond the cardiac border of the tumor and the bleeding vessels secured by forcipressure clamps, which were left *in situ*. As soon as the stomach was opened three flat sponges were introduced into its cavity which prevented the escape of any of its contents.

A second circular incision was made just beyond the pyloric end of the tumor. The cut ends of the stomach and duodenum were then closed, the mucous membrane being first roughly approximated by a continuous catgut suture, and the serous surfaces united by the interrupted Lembert sutures of fine silk. The commencement of the jejunum was recognized, and a loop which was distant about twelve inches drawn out of the abdominal cavity and placed in contact with the anterior wall of the stomach, just above its greater curvature and two inches to the left of the sutured extremity.

Before opening either the stomach or bowel the peritoneal coats of each were united by a line of continuous silk sutures three inches long. Two catgut rings (Abbe) were inserted into each viscus and secured in the usual way, the "slit" in the rings being one and three-fourths inch in length. A row of interrupted Lembert sutures was then applied on the anterior surface after tying the sutures attached to the rings. The abdominal incision was closed with silk sutures embracing its entire thickness, covered with iodoform and bichloride gauze, over which a rubber coil was applied. The anastomosis occupied twenty-five minutes, the entire operation three hours, the patient being under ether three and one-fourth hours. Toward its close the general condition was very bad, the pulse being very small and rapid, the respirations shallow and the extremities cold. She was freely stimulated with whiskey, hypodermatically, and kept with head low and legs elevated. After the operation the pulse was 160, the respiration 32. A large enema of hot water and whiskey was given. At 7.30 P.M., Magendie's solution, ♏ iv., after which she rested quietly all night. Just before the opium was given she vomited some bloody mucus. Digitalis and whiskey were given hypodermatically every three hours during the night, and another enema of hot water and whiskey. The morning following the operation the temperature was 99.4° F., pulse 136, and she was free from pain. Rectal stimulation only was allowed for two days. On the third day she took fluids by mouth, and on the tenth day solid food. The bowels moved spontaneously on the fourth day. The catgut rings were never seen. The ice-coil was discontinued at the end of forty-eight hours, the abdominal wound healing by first intention with the complication of one "stitch abscess," which caused fever on the seventh and eighth days. The gain in color, flesh, and strength was rapid. She sat up at the end of four weeks and left the hospital in the seventh week. The following table, compiled by the house surgeon, Dr. Schauffler, gives in detail the general condition, medication, and nourishment for the first eight days.

The removed tumor I am able to show you, through the kindness of Dr. Frank Ferguson, Pathologist to the New York Hospital, who reported on it as follows:

"The material consists of a portion of the stomach, down to and including the pylorus. It measures along the greater curvature, 13½ ctm.; along the lesser curvature, 7½ ctm. The pylorus and posterior wall near pylorus and greater curvature are involved by a new growth whose greatest thickness measures at pylorus, 3 ctm. The growth extends backward 11 ctm. from the pyloric incision. On the cardiac side the incision seems to have

gone several centimetres beyond the limits of the growth. The incision at the pylorus is through substance of tumor.[1] The pylorus admits tightly a cylinder 1½ ctm. in diameter. There is apparently no ulceration of growth. There are several small nodules in omentum along the line of incision.

"Microscopical examination of the small masses in omentum along the line of incision show a filiform stroma arranged into alveoli, and these alveoli are lined with epithelium. The growth in these masses, assumed to be glands, show in places an irregular appearance.

"Sections through the new growth in the stomach-wall near the pylorus show large masses of epithelium within alveoli, which vary greatly in size, some of them the size ordinarily found in carcinoma of the mamma and some of them eight or ten times that size; some areas of the new growth show a degeneration of the epithelial cells and their replacement by fibrous tissue. The muscular wall of the stomach in the line of section shows enormous thickening, including large masses of epithelium supported by a delicate fibrous stroma, some of these giving the appearance of a racemose gland. In the line of section the mucosa of the stomach is intact and greatly thickened, with its stroma infiltrated by small round cells. Many gastric tubules are atrophied and in many places the cancer masses are directly continuous with the bottoms of the tubules."

Shortly after leaving hospital this patient sailed for Ireland, where she now resides. In a letter dated November 1st (seven months after operation) she writes that she has continued to gain flesh, and is strong and well in every respect.

Case II. *Carcinoma of the Stomach; Pylorectomy and Gastro-Enterostomy; Death; Faulty Suture of Duodenum.*—J. H——, aged sixty-three, married. Had had since childhood more or less gastric trouble with marked increase in symptoms during the past year. She has suffered considerable loss of flesh and strength of late and has had frequent vomiting of food, but the bowels are not constipated and the epigastric pain not severe. Dr. Hilger, of Fort Lee, advised her to enter the New York Hospital and she was admitted August 18, 1890. Examination showed a tumor two by three inches in area just to the left of umbilicus. It was hard, not tender, irregular in outline, and freely movable. There was moderate dilatation of the stomach. Chest was found normal, the general condition good, and urine contained nothing abnormal.

The operation was performed under ether August 20, 1890, in the same manner as in the previous case. The tumor, a little smaller than the other, embraced the pylorus and greater curvature. The duodenum was on the stretch when section was made on that side of the pylorus, and when the sutures were being applied I found that the posterior wall was only in part covered with peritoneum. Its cut mucous coat was sutured with continuous catgut suture and over this several layers of Lembert sutures were applied. I realized the weakness of this step and spent half an hour in trying to make the lines of suture secure. The stomach-wound and the gastro-enterostomy were treated as in the first case. There were several enlarged glands in the omentum. The operation lasted two hours and the patient was in excellent condition at its close. For the first forty-eight hours the progress was satisfactory, then vomiting of a greenish mucus occurred, with rapid pulse and slight elevation of temperature. On the fourth day a copious discharge of yellowish watery mucus took place from the abdominal wound and this continued until death occurred on the seventh day. Only a partial autopsy was possible, but it demonstrated that the suture of the duodenum had been imperfect and permitted the discharge of this part of the intestine through the abdominal wound. The same contents had undoubtedly found their way into the stomach through the anastomotic opening and been vomited in the course of the peritonitis set up by that infection of the peritoneal cavity. The sutures of the stomach and anastomosis wound were found perfect and "water-tight." One catgut ring had disappeared, the other was found lying loose in the lumen of the anastomotic opening. The following is the pathological report in full:

"The material is the pylorus and a portion of the stomach-wall, including the first half inch of the duodenum. It measures along the greater curvature 11½ ctm., along the lesser curvature 7 ctm. Its greatest circumference is 15 ctm. There is an ulcer around the pyloric ring involving the entire circumference of the mucosa and extending upward a distance of 3 ctm. The ulcer is ½ ctm. deep.

"The greatest thickness of stomach-wall is just above the pylorus on greater curvature and is 2 ctm. in this location. The stomach-wall is infiltrated with a new formation (tumor) which extends from the ulcer above described outward to the peritoneum. The pylorus admits and grasps tightly a cylinder ½ ctm. in diameter. The mucous membrane is greatly thickened and corrugated. The line of incision is everywhere beyond tumor tissue.

"Accompanying this portion of the stomach are numerous small masses of fat, including several small glands of the same color and consistency as the tumor itself.

"Microscopically the tumor is found to be a carcinoma of the scirrhous variety the stroma being abundant and composed in part of the smooth muscular tissue of the

[1] The specimen, after removal, was handed for inspection by a number of spectators, and reached the pathologist several hours later. Its pyloric extremity was then found missing. My assistants and myself are confident that the incision was made through the healthy duodenal junction. In fact, had this not been the case, the suture as described would have been impossible.

wall of the stomach. Some of the alveoli are lined with epithelium, the cells of which are small and irregular in outline, but most of the alveoli are filled in the ordinary way.

"In places the tubules are seen to be continuous at their bottom with the carcinomatous alveoli, and in one or two instances the epithelium lining the tube seems to be directly continuous with the epithelium lining the alveoli. Nearly the entire stomach wall is invaded there remaining only a small strip beneath the peritoneum, and here in the planes of the fibrous tissue small round cells of inflammation are found. The accompanying glands are the site of beginning cancer."

The error was made in this instance of dividing the duodenum too far away from the pyloric edge of the tumor. Even in the alcoholic specimen there is to be recognized half an inch of healthy duodenal wall. All of this might properly have been left intact and been available for an efficient row of peritoneal (Lembert) sutures over the united mucous membrane.

In Case III. the suturing was, I believe, perfect, but the mortifying accident of leaving a sponge in the stomach itself led to a rupture of the line of union and peritonitis, which brought about a fatal result in fifteen hours. The patient, aged sixty-three, wife of a janitor, had been under treatment by Dr. Kletzsch of this city, who first recognized an epigastric tumor. For six months she had suffered burning pain in the epigastrium after eating, with occasional vomiting of contents of stomach and green and coffee-colored material. She was constipated unless cathartics were used, had lost flesh rapidly and become cachectic. The heart and lungs were normal and the urine presented nothing abnormal. The tumor, situated just above the umbilicus, felt on palpation to be hard, irregular in outline, movable about an inch in all directions, and two and one-half inches by four inches in area. The stomach was dilated, its lower border reaching below the line of the navel, and forty ounces of contents were removed at the first introduction of the stomach-tube. In the region of the gall-bladder a hard, small tumor was felt, which was supposed to be a cancerous deposit in the omentum. The inguinal glands were enlarged but not hard. After a few days of preparatory treatment, daily washing out of the stomach, liquid diet, and rectal injections, the operation was performed under ether, October 7, 1890, with the aid of Dr. Kletzsch, in the same manner as the other two. There was a chain of enlarged glands in the greater omentum and, what was surprising, the hard tumor in the region of the gall-bladder was that viscus itself, filled with two or three large calculi. These were not disturbed. The usual precautions were taken to prevent leaving any sponges behind. Before closing the stomach I introduced the finger three or four inches into its cavity and the "count" was declared to be correct.

The operation lasted two hours and left the patient in excellent condition, but in the course of the next ten hours there was collapse, and death with signs of commencing peritonitis took place at the end of fifteen hours. The autopsy disclosed the following important details, for which I am indebted to Dr. G. C. Freeborn, who has kindly prepared the specimen I show you:

"Abdominal cavity contains a large quantity of yellowish-green fluid. This fluid is found escaping from a wound in the greater curvature of the stomach. The omentum is found rolled up into a mass just below the stomach; it is congested and covered with fresh exudate. Liver normal in size, pale in color, but no lesions were found. The gall-bladder is enlarged, projects three-quarters of an inch beyond the free edge of the liver, and contains one large calculus and several small ones. Spleen small and pale Stomach: The pyloric end is found to have been resected, the wound is closed by sutures, the posterior two or three sutures have torn out permitting the contents of the organ to escape into the abdominal cavity. A mass is felt in the right end of the stomach, which on opening the organ proves to be a sponge. Its end rests against the situation of the torn sutures. Kidneys small, pale in color, and show gross lesions of parenchymatous degeneration. Small intestines congested and peritoneal surface covered with fresh exudate. Large intestines: Upper portion congested and covered with fresh exudate.

"The resected pylorus forms a tumor of irregular pyramidal shape, 9 ctm. long, 4 ctm. wide at its pyloric and 5 ctm. wide at its gastric extremity. On longitudinal section the walls of the stomach are much thickened, varying from 9 to 12 ctm. The bulk of this increased thickness appears to be in the mucous membrane. Microscopically the tumor is an alveolar carcinoma, the new growth extending through the entire length of the tumor and being confined to the mucous membrane. At each extremity of the tumor there is normal tissue."

The sutures were tight except those mentioned, and the catgut rings were still in place. A thin exudation concealed the silk sutures which were applied outside the catgut plates. The sponge found was a nearly round one, half the size of a base-ball.

It had been concealed in the cardiac extremity of the stomach and had escaped detection when the finger was introduced. Evidently it had been forced by the peristalsis to the region of the sutured pyloric end, and made pressure enough to tear one of the sutures.

In these operations I have departed from the typical methods in only a few details, which are, however, worthy of mention. In the preparatory treatment I have employed the stomach-pump while the patient was under ether in preference to several washings before the anæsthetic was given. This causes some prolongation of the narcosis but avoids the mental disturbance and physical annoyance inseparable from the other procedure; I should prefer the latter when patients were habituated to the tube, but I believe that the pump empties the organ more thoroughly.

The median incision has proved satisfactory and is for obvious reasons much to be preferred to any other. I have used no clamps for stomach or duodenum to prevent escape of contents; the fingers of an assistant are more satisfactory, especially if, by the aid of hooks or loops of silk the divided ends of the viscera be kept elevated in a vertical position. A plug of iodoform gauze will stop up the duodenal opening, and the flat sponges in the stomach have kept that cavity quite dry. There has been but trifling bleeding from the stomach or intestinal wall, and that which follows the incision for the anastomotic opening will be controlled effectually when the catgut rings are approximated. The loop of jejunum I have shut off with strips of iodoform gauze, while the anostomosis was being made. The continuous catgut suture through the mucous membrane, reinforced by interrupted Lembert sutures, seems to close satisfactorily the cut ends of the stomach and duodenum, but in using the rings I have always added to the silk ligatures which hold them in apposition a line of continuous silk suture, reinforced here and there by isolated sutures. I look upon the rings, *not* as an absolutely sure method of uniting the serous surfaces of the viscera, but as a most convenient adjunct to a carefully applied peritoneal suture, and in the two last cases I sutured at six points the mucous membrane, both of the stomach and jejunum, to the peritoneal coat, in order to prevent any contraction of the orifice, an event concerning the occurrence of which we know very little as yet. In all three cases the gastro-enterostomy has been perfect in point of accurate and secure apposition.

I hope these experiences may prove of use to others who may attempt these operations, and that the somewhat tedious details may help to better success than I have had thus far. I have already referred to the probability of better results in the future from adopting the newer procedures, and will close by calling your attention to some pathological data which have a bearing on the prog-

nosis of operated cases. If we consider the statistics[1] compiled by Habershon, Brunton, Gussenbaun, and v. Winiwarter, we shall find 1,342 cases of cancer of the stomach, as seen at autopsy, of which 802, or over one-half, involved the pylorus alone. The cases of Gussenbauer demonstrated that about one-half of those at the pylorus were uncomplicated by involvement of glands or adjoining viscera, or by serious adhesions.

We may say then, roughly, that one-half of the cases of pyloric cancer presented on autopsy conditions favorable for operation. Streit,[2] at the Berne Klinik, found of fifty-four cases, between the years 1876 and 1886, twenty-five per cent. presenting similar conditions. The percentage would naturally be greatly increased at an earlier period in the disease.

It is just to believe that in cancer of the stomach we have to deal with a neoplasm of slow growth, with slow tendency to infiltrate the neighboring parts, which often causes death by mechanical obstruction before its victim is overtaken by general exhaustion. Is it not our duty to discover and attempt to cure such a condition at a much earlier period of its growth? The physician by the frequent chemical examination of the stomach contents, the hydrochloric acid test, together with careful and frequent abdominal palpation, will help to this early diagnosis, while the surgeon may, by means of exploratory laparotomy, safely determine the nature, seat, extent, and complications in doubtful cases. With these aids, which at present are too often long delayed or quite neglected, we shall have in the future a far better opportunity of dealing with this fatal disease; and pylorectomy, or some of its modifications with their improved technique, will be raised from its present position of doubt and uncertainty to that of a life-saving and life-prolonging operation.

CEREBRO-SPINAL MENINGITIS IN AN INFANT DUE TO THE DIPLOCOCCUS PNEUMONIÆ OF FRAENKEL AND WEICHSELBAUM.[3]

By L. EMMETT HOLT, M.D.,
AND
T. MITCHELL PRUDDEN, M.D.,
NEW YORK.

Similar cases to the following one have already been reported in German medical literature, but this is believed to be the first one recorded in this country.

Clinical History (Dr. Holt).—The patient was a female child, thirteen months old, an inmate of the New York Infant Asylum. She was, previous to the illness here recorded, in excellent condition and nursed by the mother; there had been a slight cough but no other symptoms prior to October 8th. While standing in her crib on the afternoon of this date, the side became detached and the child fell to the floor a distance of about two feet, striking upon the chest and forehead. She cried considerably but in two hours was bright and in all respects natural. There was an attack of vomiting during the night, but she slept quietly and the next morning seemed perfectly well, excepting that ecchymosis existed beneath the left eye. Nothing abnormal was observed during this day until toward evening, when she became very fretful and feverish and at eight o'clock she was taken with severe vomiting which was repeated at short intervals during the night. The temperature rose rapidly to 103° F., and from this time remained steadily high. Slight convulsive movements of the face were observed once during the night.

From the onset of severe symptoms and vomiting the illness lasted just eighty hours. Vomiting persisted during the whole attack; the bowels moved regularly once or twice daily. The temperature remained steadily high, from 102.5° to 105.5° F.; pulse rapid, but regular; respirations 48 to 54 per minute. The prostration was very marked and steadily increased. General cyanosis was quite prominent throughout the illness; this, with the rapid breathing and persistent high temperature, led to the suspicion of pneumonia, but repeated examinations of the chest revealed only very rude respiration on both lungs, no râles and no signs of consolidation.

There was, for the first two days, general nervous irritability, but no delirium. During the last eighteen hours only were there any decided nervous symptoms. Drowsiness was first observed, this gradually merging into stupor; with this there was a slight amount of rigidity in the lower extremities, and a little later convulsive twitchings were seen in the right face and arm. The stupor steadily increased and she died comatose. There was at no time opisthotonos, retraction of the abdomen, pupillary disturbances, or constipation. The prominent symptoms were persistent high temperature, vomiting, prostration, and cyanosis, with the nervous symptoms above noted during the last eighteen hours.

Autopsy, seven hours after death. Body well nourished. Large ecchymosis beneath left eye, but bone and dura mater normal in the corresponding region; no subdural hemorrhage; non-adherent thrombi in the superior longitudinal and lateral sinuses, thrombi in many of the cortical veins leaning to these sinuses. There was a very abundant exudation of lymph and pus which enveloped completely the anterior half of the brain; posteriorly it was seen in scattered patches. Exudation rather less abundant at the base than over the convexity. Lateral ventricles not distended with fluid. The spinal canal was lined by a thick layer of fibrin and pus, chiefly posteriorly, the exudation being rather more abundant above than below. The dura externally was covered with this exudate upon its posterior and lateral surfaces, but none was present in front. The inner surface of the dura and the pia mater were congested, but otherwise normal. No tubercles in brain or cord. The lungs were uniformly congested, but there were no areas of consolidation or collapse. Pleura normal. The heart contained adherent decolorized thrombi, which extended into the pulmonary artery and the aorta. Pericardium normal. Spleen slightly enlarged, otherwise normal. Liver normal. Kidneys showed moderate cloudy swelling of cortices. Alimentary tract normal.

Bacteriological and Microscopical Study of the Brain and the Lungs (Dr. Prudden).—Cultures were made five hours after the autopsy from both the brain and the lungs, on plates of agar and glycerine-agar, and kept in the thermostat at the body-temperature. On the plates made from the exudate of the pia only one variety grew, and that in large numbers. This growth on the agar plates was in the form of grayish, inconspicuous, translucent small colonies, which very soon died out and could be no longer transplanted with success.

Transfers made to tubes in from twenty-four to thirty-six hours showed the same growth on agar. There was no growth on gelatine at the room-temperature, and no growth on potatoes.

Morphologically these germs were very short, often lance-head shaped, and mostly in pairs, presenting, however, considerable variation in shape, the diplococcus form predominating.

Inoculations were made either subcutaneously or into the pleura in white mice (two animals), and death ensued in about thirty six hours. The post-mortem examination showed a moderate fibrinous exudate of the pleuræ, congestion of the posterior lobes of the lungs, and a large, soft spleen. The blood from the heart and the exudates showed large numbers of short-paired bacilli with translucent capsules.[1]

A replanting of the exudates and blood from the heart gave a new set of pure cultures similar to those made from the brain of the child. Cultures from the child's

[2] Loc. cit.
[3] Presented to the New York Pathological Society October 22, 1890.

[1] These were shown to the Society.

lungs showed the prevailing bacterium to be the same as that which was so abundant in the cerebral exudate.

The morphological, biological, and pathogenetic characters of this germ, then, suffice for its identification as the diplococcus pneumoniæ of Fraenkel and Weichselbaum.

Sections of the inflamed pia, stained for bacteria, show that in places the exudate, pushing apart the layers and fibres of the pia, is crowded with the pneumococcus. The lung shows, in addition to its congestion, a very slight amount of exudation here and there into the air-vesicles, and a moderate degree of inflammation of some of the smaller bronchi.

Remarks.—It seems to be pretty well established by the researches of the past few years that the pneumococcus of Fraenkel and Weichselbaum is the bacterial etiological factor in the infectious disease, acute lobar pneumonia. But these same researches have shown that the diplococcus pneumoniæ has another and a very significant rôle among the pathogenic bacteria. It has been repeatedly found either alone or in association with other germs in several of the not infrequent complicating lesions of acute lobar pneumonia, such as suppurative meningitis, endocarditis, etc. It has been also shown that, apart from pneumonia, this germ is capable of setting up suppurative inflammations in various parts of the body, as in the middle ear, joints, etc. The case is an excellent example of this particular lesion of the brain and cord which has already been shown in a considerable number of cases to be associated with the pneumococcus.

Two points are worthy of notice in connection with the clinical history. The first is the early predominance of pulmonary symptoms, rapid breathing, cyanosis, etc., and those of a cerebral character. This appears to show that the effects of the infection were felt to a considerable degree in the lungs, even though the principal lesions were in the central nervous system. This seems not unnatural, since the diplococcus is more frequently the cause of pneumonia than of other inflammations.

The second point is the rôle played by the traumatism. This was definite and quite severe and occurred just twenty-four hours before the onset of active symptoms. Was it simply a coincidence? It seems more likely that this may have been the factor which determined the brain, rather than any of the other organs, as the seat of disease.

No other cases of cerebro spinal meningitis had been seen in the institution for a year, and no cases of pneumonia have occurred this season in the building which this infant occupied.

A CONSIDERATION OF PROFESSOR KOCH'S METHOD OF TREATING PULMONARY TUBERCULOSIS.

Some of the Complications Apt to Arise—Some of the Dangers to be Apprehended.

By JOSEPH WILLIAM STICKLER, M.D.,

ORANGE, N. J.

In preparing this article for publication it seemed to me wise to endeavor to reproduce as clearly as possible my experience in the Berlin hospitals while studying the effect of Koch's "lymph" upon patients suffering from pulmonary tuberculosis. I have therefore selected three instructive cases which I have reported, *in extenso*, giving all the daily happenings, hoping and believing that those who read them will learn more about this new method than if a great variety of opinions were quoted. Each man must and will form his own opinions, but to do so he must have all the facts, so far as he can procure them, in relation to cases treated. And let me say here that the profession on this side of the Atlantic should not at once adopt this new treatment of tuberculosis and lupus without using the utmost caution, for it is not without its dangers, I may say very great dangers, neither has it yet been shown to be a cure for tuberculosis of the lungs. That many patients seem to be better there is no doubt. Let us trust that ultimately they may be cured. That some patients are worse than before they were treated is equally true. That others have died while being treated is just as true.

In an interview with Professor Virchow, he told me that several patients had been killed by the lymph, for which reason, and also because dangerous complications sometimes arise, he urged very great caution in the use of the remedy, suggesting that small doses be frequently employed rather than large ones at short intervals, as has been done, especially in lupus. There are physicians who think that almost any case of incipient phthisis may with perfect safety be injected with Koch's lymph. Experience in Berlin leads me to say, examine such a patient *very* carefully, not only his or her lungs, but the larynx as well, for if there be any tubercular disease in the latter organ the lymph will find it, and may cause such an infiltration and œdema of the soft tissues as to necessitate tracheotomy. Then, again, should there be any tubercular tissue in the lungs, not discovered prior to injection, it would be promptly influenced by the lymph and thus the patient be made worse, at least for a time. By being made worse, I mean that there would be dyspnœa, a pulse of 120 or perhaps 160, a temperature of 102° to 104° F., and great prostration, possibly a comatose condition, as in a case I saw in the Charité Hospital in Berlin. On the other hand, the lymph should be used, and cautiously, upon a great variety of tubercular affections and results carefully and accurately recorded. At the present time these trials should be made, with but few exceptions, in hospitals or institutions where medical attendance is constant, and where dangerous complications may receive prompt attention.

That Professor Koch has given us a remedy of great power, and one whose selective action is upon tubercular tissue, whether external or internal, there is no doubt, and we honor and praise him for his wonderful discovery; but let us by a careful consideration of the facts thus far supplied, and by a searching and exhaustive trial of the lymph in other cases, get at the whole truth, so far as we may, in relation to this interesting matter. All spirit of prejudice and preconceived notions should not find a place in our mind while thus seeking for the truth. Let us, then, follow carefully the records of the cases given in this article, together with the charts, and then, adding what information may thus be gained to what has been or will be gained from other sources, opinions may be formulated and conclusions arrived at.

Case I.—Female, aged twenty-one. Father died of phthisis, also brother when he was twenty-six years of age. She had measles and scarlatina when young. Menses appeared when twelve years of age; they were irregular. Has had no children. About four months ago had cough and pain in chest. Pain most intense in right shoulder. For six months has been hoarse, at times aphonic. Expectoration is purulent. At first but small amount in morning. During the last few weeks has had night-sweats. There has been no hæmoptysis. Appetite poor—has lost but little in weight. As a young child had some glands extirpated. Has had a syphilitic exanthema, but no sign of syphilis on November 22d, the date of admission into the hospital. Her thorax is normal in shape, and the intercostal spaces show no changes. There is consolidation of the right apex. Moist râles may also be heard on right side. The sputum is globular and very hard. There is a soft systolic anæmic murmur. The larynx is normal—the vocal cords are slightly uneven.

On November 25th there was no rise of temperature. There were many tubercle bacilli in the sputum.

On November 26th, 10.45 A.M., she received under the skin of the back 2 milligr. of Koch's lymph. At 6 P.M. the temperature was 38.7° C., but fell to 37.2° C. by 9 P.M. The next morning at three o'clock the temperature

was 38.4° C.; in the afternoon at three o'clock it was 37.2° C., and in the evening at nine it was 38.1° C.

On November 27th two characteristic symmetrical ulcerations appeared on the vocal cords.

November 28th. 6 A.M., temperature was 36.2° C. At 9.30 A.M. 5 milligr. of lymph were injected. At 6 P.M temperature was 37.9° C.

November 30th. 10.15 A.M., 10 milligr. of lymph given. Temperature at 9 P.M., 39.8° C.

December 1st. A.M., temperature, 38.1° C.; 9 P.M., 36.3° C.

December 2d. 9.45 A.M, injected 10 milligr. of lymph. Temperature, 6 P.M., 38.9° C., at which point it remained till 9 P.M., when it began to descend, reaching at twelve o'clock 37.4° C.

December 3d. 6 P.M., temperature, 38.3° C.

December 4th. 12.30 A.M., 12 milligr. of lymph injected. Temperature at 6 P.M., 39.7° C.

December 5th. 12 P.M., temperature, 36° C.

December 6th. 9.30 A.M., injected 12 milligr. of lymph. Temperature, 9 P.M., 38.4° C. At six o'clock next morning temperature 38.5° C.; at twelve o'clock, 38.8° C.

December 8th. 6 A.M., temperature, 36.2° C. At 11 A.M. gave under the skin 15 milligr. of lymph. 9 P.M., temperature, 38.5° C. The temperature then slowly receded till on December 10th, 9 A.M., it stood at 36° C.

December 10th the ulcers on the vocal cords were entirely healed. At 9.30 A.M. of this date (10th) 15 milligr. of lymph were injected. Temperature at 12 P.M., 38.1° C. It descended slowly till on December 13th it was 35° C.

December 13th. 10.30 A.M., injected 15 milligr. of lymph. The evening temperature was 39.1° C. The temperature, December 15th, was 35.6° C. During all this time the pulse occasionally went up to 120.

December 16th. 11.30 A.M., injected 15 milligr. lymph. Reaction very slight, 38.1° C.

December 18th. 10.45 A.M., injected 18 milligr. lymph. No reaction. On December 8th and 13th, during the reaction, the respirations were 58. On November 28th she weighed 95 kilo.; on December 3d, 93 kilo.; December 7th, 92 kilo.; December 10th, 93 kilo.; December 15th, 94 kilo. She is gaining in weight. Since the injections were begun there has developed at the base of the right lung a lobular pneumonia. It developed on December 11th. This condition is supposed to be produced by the inoculations. She expectorates but little.

Case II.—Charles K——, aged twenty-four, painter. Mother died of tubercular phthisis. Father had phthisis. One brother is living and well. As a child he had enteric fever, measles, and scarlatina. Since that time has been well till the development of his present disease. His present illness began in September, 1890, with cough and moderate expectoration. At the end of September he had a hæmoptysis—one-half teacupful. During that month he also had night-sweats with an afternoon chill.

At the time he entered the hospital, October 30, 1890, he had cough, pain in chest on deep inspiration, and a feeling of weakness. Present condition, strongly built man. Skin dry and pigmented. No infiltration of glands. Face flushed. Pulse regular, 72 per minute. Appetite good; tongue coated. Liver and spleen normal. Thorax well arched; the supra- and infra-clavicular regions rather deep; percussion-note shorter at left apex, at supra- and infra clavicular spaces than on the right side; dull also posteriorly at left apex; auscultation shows bronchial expiration anteriorly over left apex; many moist râles on expiration; posteriorly over left lower lobe there is evident pleuritic friction from seventh vertebra downward, accompanied with very weak respiratory sounds. Vocal fremitus also somewhat weakened. Heart normal; vital capacity 2,000 c.c. On November 6th a small ulcer of the left arytenoid body was noticed. November 10th, dulness still persists at left apex. In left fossa supraspinatus bronchial breathing and occasional consonant râles. The affection of the left lower lobe shows signs of improvement. Tubercle bacilli quite numerous in the sputum. From October 31st to November 18th his temperature was always normal. His weight on November 18th was one hundred and twenty-six pounds. The condition of the lung the same as on November 10th.

November 18th. 8 A.M., he received of Koch's lymph 0.002 gm. Temperature gradually rose till 5 P.M., when it reached 38° C.; at 6.30 P.M., temperature, 39° C.; 8 30 P.M., 39.5° C.; 9.30 P.M., 39° C.; 10 P.M., 38.3° C. It then gradually fell during the next twenty-four hours till it reached, on the morning of the 20th, 36.4° C. The first subjective signs of the reaction following the injection of 0.002 gm., November 18th, were observed at twelve o'clock, four hours after treatment. First noticed flushing of the face, which condition was accompanied with a feeling of feverishness. At five o'clock same day patient complained of pain in left tibia, and an exanthem (like measles) associated with itching appeared upon the face. At seven o'clock there was a profuse perspiration, the pulse became dichrotic, the conjunctivæ congested, and the exanthem more pronounced. At eight o'clock he complained of lancinating pain in left apex.

On November 20th he felt well and his vital capacity was 1,800 c.c. On this date he received 0.003 gm. of lymph and showed no reaction of temperature. Had a slight constitutional disturbance, cough was increased, the exanthem in the evening quite prominent, and the sputum 40 c.c. in quantity.

On November 21st the right arytenoid body shows a grayish-white discoloration.

November 22d. Injected 0.005 gm. of lymph. There followed no particular reaction of temperature, pulse, or respiration. The tubercle bacilli showed no morphological changes but they were not present in great numbers. He complains of pain in the neck and oppression of chest.

November 24th. Received 0.008 gm. of lymph at 10 A.M.; at 7 P.M., temperature, 38.5° C. There was slight constitutional disturbance. The right arytenoid body shows slight ulceration. Both vocal cords are injected. Sputum, 60 c.c.

November 26th. 10 A.M., gave 0.010 gm. of lymph. There was scarcely any reaction of temperature. The sputum now changed from its former numulated and purulent character into a frothy and muco-purulent condition. Quantity, 30 c.c., just one-half the quantity recorded on November 24th.

November 27th. The exanthem on the face very evident in the morning. The ulceration on the right arytenoid body still present. The injection of the vocal cords not so well marked. Quantity of sputum, 10 c.c.

November 28th. Injected 0.015 gm. of lymph. There was a slight reaction of temperature. Temperature after injection, 38.2° C. At this time only one bacillus could be found on two slides. Lung changes: Dulness at left apex still present; bronchial breathing confined to the upper portion of left supra-spinous space. A few mucous râles, especially in the fossa infra-clavicularis of left side.

December 2d. 10 A.M., injected 0.025 gm. of lymph. There followed a slight reaction of temperature, 38.1° C. Pulse and respirations unchanged; the catarrhal condition of the larynx greatly improved; the ulceration of the left arytenoid body not as evident as before.

December 3d. The anterior pillars of the fauces very red, and show a number of whitish patches, probably herpetic.

December 4th. 10 A.M., gave 0.030 gm. of lymph. Temperature in the evening, 38.3° C.; sputum, 20 c.c. General disturbance very slight. Weight 131 pounds; weight November 18th, 126 pounds, a gain of 5 pounds.

December 5th. Sputum, 80 c.c., twice as much as on November 28th.

December 6th. 10 A.M., gave 0.040 gm. of lymph.

Temperature, 6 P.M., 38.5° C.; sputum, 40 c.c.; constitutional disturbance slight. No tubercle bacilli to be found in four specimens.

December 8th. 10 A.M., injected 0.050 gm. of lymph. Temperature. 6 P.M., 38.4° C.; sputum, 20 c.c. It will be noticed that the quantity of sputum varies, sometimes more, sometimes less.

December 10th. 10 A.M., injected 0.060 gm. of lymph. Temperature, 6 P.M., 38.8° C.; sputum, 20 c.c. New appearance of exanthem on face. The laryngeal ulceration which had healed became visible again. No tubercle bacilli present in one specimen. Vital capacity, 1,950 c.c.

December 11th. Only day when the temperature was 38.1° C. without injection.

December 12th. Injected 0.070 gm. of lymph. A typical reaction followed, 39.4° C. Had a night-sweat. Dulness at left apex still evident. Bronchial breathing no longer detected; only occasional râles; sputum, 20 c.c.; severe headache.

December 14th. Injected 0.070 gm. of lymph. Temperature, 6 P.M., 38.4° C. General disturbance slight.

December 16th. 10 A.M., injected 0.080 gm. of lymph. Temperature, 6 P.M., 38.9° C.

Since December 15th only 10 c.c. sputum daily. At present catarrhal condition of apex greatly reduced. Only at one spot is there slight bronchial breathing on expiration. No more night-sweats. Weight, 132 pounds. No bacilli found in several specimens.

CASE III.—Caroline M——, aged twenty-eight, housewife. Comes from tuberculous family; mother died at forty-two of tubercular pleurisy; father living and well; one brother has phthisis, one brother and sister well; menses began at fifteen, and were irregular till nineteen; pregnant since July 1, 1890; has had five children, two living; one died three and one-half days after birth; had two abortions, one at third, and one at sixth month. One year ago present disease began. There was much cough, with small amount of frothy mucoid expectoration; lancinating pain in right shoulder below the clavicle. Once weighed one hundred and twenty-six pounds; has lost much in weight during the last year; has no night-sweats. Condition on December 2d: Complains of great weakness; has considerable expectoration; sleeps but little; vomits, and has pain in her back. She is a small woman with a weak muscular system; skin dry and non-elastic; she has no exanthem or anasarca; the anterior pillars of the fauces are redder than normal; pharynx normal, no glandular swellings. Condition of lungs: Percussion at both apices normal; posteriorly over left scapular spine, slight dulness; there is also some dulness on right side in same region. Above the left spine (scapular) there is harsh vesicular breathing, and prolonged and blowing expiration with large and small râles. Over the right scapular spine there is rather harsh inspiration, and a blowing expiration, no râles; over the rest of the lung there is vesicular breathing. Over the left clavicle occasional râles, also under the clavicle down to the third rib râles may be heard. She coughs a great deal and expectorates a large quantity of purulent and nummulated sputum containing many bacilli. Heart normal, second sound accentuated. Pulse 100 to 110. Epiglottis relaxed.

December 3d. 10 A.M., injected 0.002 gm. of lymph. Cough increased, also headache and weakness. Expectoration slightly increased. Temperature reached only 38° C. Dulness of left apex became more evident; vesicular breathing very harsh; vocal cords normal.

December 4th. Temperature normal. Patient feels comparatively well. Less expectoration and no night-sweats. Sleeps well and appetite good.

December 3d. Weight, 42 kilo.

December 5th. 10 A.M., injected 0.005 gm. of lymph. Temperature rises from 36.1° C. to 37.4° C. at 6 P.M. Pulse rises from 95 to 120. No laryngeal changes.

December 6th and 7th. No complaints, except moderate nausea. Cough and expectoration decreased. Moderate diarrhœa.

December 8th. 11 A.M., injected 0.007 gm. of lymph. No reaction. Very little expectoration and cough.

December 9th. Patient has no complaints.

December 10th. 11.15 A.M., injected 0.008 gm. of lymph. No reaction. No complaints. Tubercle bacilli in two specimens, in small numbers. But little expectoration.

December 12th. Injected 0.010 gm. of lymph. No reaction. Slight diarrhœa. Expectoration has entirely ceased. Has a slight cough in early morning.

December 15th. Injected 0.015 gm. of lymph. No reaction. Not much cough. No expectoration.

December 17th. Injected 0.020 gm. of lymph. No reaction. No night-sweats. A little cough toward morning. Weight has increased to 43.5 kilo., a gain of three pounds.

Remarks upon these Three Cases in the Order in which they are Reported.—Case I. The patient, a young woman, had a very bad family history, father and brother having died of tubercular phthisis, hence the inherent tendency to a fatal issue in the case under consideration is pronounced. She had syphilis, and was of a scrofulous diathesis. She had consolidation of the right apex and indications of involvement of a portion of the lung below the apex. There were many bacilli in her sputum. Characteristic tubercular ulcerations unexpectedly appeared upon the vocal cords on the day following the first injection of lymph. No typical reaction obtained till 0.010 gm. of lymph were given (subcutaneously). The rise and fall of temperature following the injection of the lymph was comparatively gradual. The ulcerations on the vocal cords healed in thirteen days. Large doses of the lymph increased the action of the heart to one hundred and twenty beats per minute. Her expectoration is reduced in quantity. While she seems to be improved in some respects, she really has more disease to combat and recover from than before she had the inoculations. The lobular pneumonia at the base of the right lung is pronounced, and did not exist prior to the use of the lymph. Taking everything into consideration, the opinion prevails that she will ultimately die.

Case II. Family history very bad in this case, both parents having died of phthisis. He had quite a free hæmoptysis and his disease made quite rapid progress. He had tubercular ulceration of his larynx as a complication. Tubercle bacilli were quite numerous in his sputum. His weight on the day of his first inoculation, November 18th, was 126 pounds, on December 16th 132 pounds, a gain of 6 pounds. In September he had night-sweats, afternoon chill, cough, expectoration, pain in his chest, and a feeling of weakness. On December 16th he complained of no night-sweats, no afternoon chill; the expectoration was greatly reduced in quantity, and he feels stronger. On October 30th he had dulness over left apex and bronchial breathing, also râles. On December 12th dulness at left apex still present, but bronchial breathing no longer detected. However, on December 15th bronchial breathing is again detected on expiration. Tubercle bacilli were found in his sputum on November 10th; none were found in several specimens on December 15th. The introduction of Koch's lymph caused an increase of cough, expectoration, fever, an exanthem, pain in left apex, profuse perspiration, and a dichrotic pulse. These conditions, however, disappeared in due time.

Congestion of the vocal cords was one effect of the treatment. A herpetic eruption upon the anterior pillars of the fauces was also produced. This man when questioned as to his general condition said, "I feel weak, no appetite; I feel no better." He certainly appeared to be in good condition. His face had a good color, his eyes had a natural brightness, and he was actively engaged in the ward.

Case III. This patient has a tubercular family history, her mother having died at a comparatively early age

(forty-two) of phthisis. The only case of pregnancy thus far inoculated (that I know of).

The use of the lymph has not in any respect interfered with the normal progress of pregnancy. At one time prior to treatment she coughed a great deal, and expectorated a large quantity of sputum containing many bacilli. On December 15th, but little cough, and no expectoration. The injections increased the cough and expectoration. It also increased the dulness at the left apex. In this case no laryngeal changes occurred. Her condition really seems to be improved both locally and generally. It must not be forgotten, however, that pregnancy oftentimes produces a favorable influence upon phthisis.

Complications Apt to Arise in the Course of Treatment, and Some Facts to be Remembered in Connection with the Use of Koch's Lymph.—Children are apt to have diarrhœa. Vomiting sometimes occurs in adults, more likely to occur in the young. These conditions usually disappear in a few days. They are probably due to the septic effect of the lymph. An exanthematous rash, sometimes like scarlatina, sometimes like measles, occurs not infrequently. It always is of temporary duration. Albuminuria occasionally develops after the use of the lymph. It has not been excessive as yet. Herpes labialis sometimes accompanies the use of the remedy. Children are liable to rigors. All persons do not react to the lymph in the same manner, although they may be suffering from the same form of tuberculosis, and in persons suffering from laryngeal and pulmonary tuberculosis the reaction presents very different features. The soft tissues of the larynx are apt to be quickly infiltrated or œdematous, so that tracheotomy may have to be performed. Casts have never yet been found in the urine after injection; there has never been suppression of urine; the specific gravity is the same as in ordinary fever. The bowels are sometimes constipated; usually regular in adults. Hæmatemesis has never occurred, but hæmoptysis has in progressive cases, after the third or fourth injection. Headache is toxic. The eruption is apt to come after the fourth or fifth injection. There have been no sudden deaths clearly due to the action of the lymph. There may be an infiltration of the tissues without a true œdema. The lymph when introduced into the system may cause a very high temperature and a hectic much above the normal hectic. Exercise is desirable after injections, for it increases the appetite, and acts psychologically. All the vital forces are usually depressed by the lymph, hence the patients complain of languor. Languor is proportionate to the reaction after injection, but it may obtain when no reaction shows itself. Aphasia is probably caused by infiltration of the retro-bronchial glands, which press upon the recurrent nerve. In one instance aphasia lasted three weeks. There has been no local paralysis or violent delirium. The comatose condition sometimes occurs. The appetite improves when the reaction is not pronounced. Living tubercular tissue is affected by the lymph, not the tubercle bacilli, therefore after treatment the bacilli may be absorbed with tissue which has been necrosed and thus be a means of starting new centres of disease; or they may remain where they were when treatment was begun, in which case after absorption of the necrosed tissue they would be in a fresh nutritive medium and cause a fresh outbreak; or the necrosed tissue may not be absorbed and the bacilli die in it from lack of nutrition (Koehler). The absence of bacilli does not contra indicate injections of the lymph.

It ought to be said that the injection of the lymph has in several instances caused death, thus far five times in the Charité Hospital, Berlin. These deaths have occurred in the advanced stages of pulmonary tuberculosis. In one instance the use of the lymph induced a fatty condition of the heart, followed by cardiac failure. Should a tubercular patient have an irritable heart, or a very weak heart, very great caution should be used in injecting the remedy, large doses never being used with safety under such circumstances.

KOCH'S METHOD OF TREATMENT FOR TUBERCULOSIS, FROM PERSONAL OBSERVATIONS IN BERLIN.[1]

By MAX EINHORN, M.D.,

PHYSICIAN TO THE GERMAN DISPENSARY, AND INSTRUCTOR IN CLINICAL MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

GENTLEMEN: It is in the nature of the subject that I am not able to bring to you to-night much that is original. I have only accepted the kind invitation of our esteemed president to discuss this theme, in order to give you a *résumé* of the lymph treatment in Berlin.

Koch communicated, in his well-known paper on "Bacteriological Investigation," read at the last International Medical Congress, that he had succeeded in making guinea-pigs immune against vaccinations with the tubercular virus by inoculations with a certain substance, notwithstanding the fact that the guinea-pigs are known for their extraordinary susceptibility for tuberculosis. Likewise, that he was able to check the disease in guinea-pigs with general tuberculosis without any injury whatever to the body. Koch at that time finished his speech with the following words: "Should the hopes connected with these experiments become realized, and should we succeed in overcoming the microscopical but potent enemy in the human body, though at first in but one bacterial infectious disease, then we would no doubt very soon become enabled to accomplish the same in other diseases also. In this way a very promising field of labor will be opened, with incentives worthy to form an international contest of the noblest kind."

Now that Robert Koch has shown, in his memorable paper of November 13, 1890, that he has discovered a remedy for tuberculosis of man, it is no wonder that the attention of the whole world has been directed to this discovery. No wonder that not only physicians, but also laymen, wished to be minutely informed of every detail pertaining thereto.

This discovery of Koch to cure the disease of the tubercle bacilli gave hope, and even the probability, that we shall soon succeed in other infectious diseases also to fight with similar means against the disease producers. Hardly had we as yet recovered from that agreeable surprise when we heard that there was a possibility of making animals immune against diphtheria and tetanus.

To-night the discussion might be limited to Koch's treatment for tuberculosis.

Koch in his treatment for tuberculosis administers a remedy, the composition of which he has not as yet made public. This, which goes under the name of "Koch's lymph," or "Koch's fluid," or "Kochine," consists of a dark brownish, clear fluid, which gives no precipitate when heated to the boiling-point. It is generally believed that the main efficacy of the remedy consists in certain toxalbumins produced by bacteria. Although it is not probable, according to the suggestion of Dujardin-Beaumetz, that this product originates from the tubercle bacilli, inasmuch as guinea-pigs (who react quickly and promptly on traces of tubercle-bacilli) can stand the medicament in much larger doses than men, the toxalbumin contained in the remedy may, however, be the product of other micro-organisms, which are less noxious to guinea-pigs than to man.

Whatever the composition of the Koch fluid may be, it is certain that it acts in a specific way in tuberculosis. When brought into the organism of a tuberculous patient it causes inflammation of the tissue surrounding the tubercle-bacilli, with resulting necrosis, and produces fever even when given in small doses. This specific effect of the medicament is diagnostically of high value; it serves to corroborate the diagnosis of a tubercular affection.

The fever which arises a few hours after the inoculation of Koch's lymph is probably not due solely to the

[1] Read before the German Medical Society of New York, January 5, 1891.

resorption of decomposed tubercular tissue, as Litten believes, but must be ascribed rather to a combined effect of the medicament in alliance with certain products of the decayed tubercular tissue. The medicament itself in larger doses (over one centigramme) is, even in healthy, not tuberculous people, of a pyogenetic nature; combined with certain products of the tubercular tissue it gains in strength and displays, even in much smaller amounts, the quality of producing fever.

The method of the new Koch treatment for tuberculosis as yet cannot be considered as perfect in every way. It has been given by the discoverer of the new remedy merely in its main features. The principal and most important point consists therein that the Koch fluid has to be incorporated into the sick organism by hypodermatic injections. These have to be continued so long and in increasing doses until the affected organism can stand them without reaction in as large amounts as a perfectly healthy, not tuberculous individual. When this point is reached the treatment can be considered as finished.

The way and mode of using the remedy, even when done for merely therapeutic purposes, is as yet experimental. In giving you the following description of the method of the Koch treatment generally practised in the Berlin clinics I beg of you not to consider the assertions as unchangeable rules. On the contrary, it would be advisable to give every new idea, in reference to some modification of the method, a trial.

The different kinds of tuberculosis may be aptly classified as to the Koch treatment, as follows: (*a*) Lupus, tuberculosis of the skin; (*b*) tuberculosis of the joints, bones, and glands—surgical tuberculosis; (*c*) tuberculosis of the larynx; (*d*) tuberculosis of the lungs; (*e*) tuberculosis of other internal organs—brain, bowels, kidney, bladder, etc.

Lupus: the surgical and larynx tuberculosis form that field where the proceeding changes after the incorporation of the remedy can be very plainly observed, and where positive results have already been obtained. In lupus and in the surgical tuberculosis they begin in Berlin, provided that the patient is otherwise a healthy and robust individual, with large doses; 0.01 milligr. of the lymph is usually given in the first injection. If there follows a strong reaction (temperature of 40° C. and above), which is almost the rule, the same dose is repeated after the patient has perfectly recovered from the reaction, and had an interval of one day with normal temperature. But if the reaction after the first milligramme was only slight (temperature of 38° C.), in the next injection a larger dose is given.

In tuberculosis of the lungs and the larynx one proceeds much slower with the doses of Koch's remedy. As a rule one begins with one, at the utmost with two milligrammes and increases in the way of milligrammes.

Cases of meningitis tuberculosa are hardly appropriate for Koch's treatment, in fear of an eventual œdema or hyperæmia of the brain.

As regards the tuberculosis of the other internal organs there are as yet only few experiences, and it is necessary to begin with milligrammes.

The phenomena which are observed on the patients after the injection are classified into such of local and such of general nature, "local" and "general reaction."

In lupus, the surgical tuberculosis and the tuberculosis of the larynx, the local reaction can be best observed. A short time after the injection (sometimes after one hour and even earlier), there arises a reddening and swelling of the diseased spot, combined with an elevation of the temperature on the same place. This local reaction appears everywhere in the tissue surrounding the tubercle bacilli and consists in an acute inflammation of the same with issue in necrosis.

In the tuberculosis of the lung the local reaction, although concealed to the eye, can nevertheless be very well observed. The patients feel, sometimes, an oppression in the chest and must often cough much more; objectively there can be found in the greatest majority of cases an increase of the abnormal auscultatory phenomena.

The general reaction appears in all kinds of tuberculosis in a like way; it begins four to five hours after the injection, and consists in a general fatigue, uneasiness, shivering, fever, and several other phenomena which are the consequence of the fever (nausea, vomiting, etc.). The fever can attain very high degrees, especially after large doses of the remedy. Sometimes there occur, very shortly after the appearance of the fever, exanthems on the body; most often herpes and roseola have been observed; more seldom the scarlatinous exanthema with a consequent typical degeneration of the skin. The increased temperature usually lasts only a short time and soon returns to the normal; sometimes after the decrease there is another elevation of the temperature, and this may be repeated under certain circumstances several times. The picture of a patient with a strong general reaction reminds one of the symptoms of an acute septicæmia.

In reference to the results obtained by the Koch treatment, they are in a high degree satisfactory in lupus, the surgical and laryngo-tuberculosis. One can see how stiff joints become movable, fistulas disappear, and cicatrices develop on ulcerated spots. Nobody, however, is able to tell whether there would not be any relapses. In tuberculosis of the lung in the middle stage there appears sometimes (after the point at which no reaction has been reached) a visible amelioration in the condition of the patient. The expectoration is diminished, the night sweats cease, and the fever does not make its appearance. It is, however, at present, impossible to say how much of the amelioration may be due to suggestion, and how long the ameliorated condition will last. The advanced stages of tuberculosis are not appropriate for the Koch treatment, because a more rapid development of the process may sometimes arise after the injections.

All cases included in the category of beginning phthisis, however, should be subjected to the Koch treatment. In Koch's department at the Moabit Hospital there were two girls with tuberculous apex catarrh, in which all pathological symptoms, even objective, disappeared completely after two months of treatment, and who for the present may be regarded as cured.

Having roughly presented to you the main features of the Koch treatment, I now desire to call your attention to the dangers and complications which may arise upon its administration.

Large doses (1 ctgm.) readily induce collapse. In two of von Bergman's cases with tubercular joint disease I saw temperature of 41.5 C. (107° F.), and over, and the patients in a condition of extreme collapse which was only combated by most vigorous stimulation, thereby preventing a fatal termination. Even with smaller doses, under some circumstances, collapse may supervene. Let me call your attention to the case at Innsbruck, a young girl of sixteen years, suffering from lupus, who after the first injection of only 2 milligr. developed a temperature of 107° F., with sopor and collapse, and died at the end of thirty-six hours.[1]

In tuberculosis of the larynx we may see œdema of the glottis, necessitating tracheotomy.

In cases of pulmonary tuberculosis hemorrhages have frequently been observed, still they were never of a very serious nature.

The danger of general infection through distribution of the bacilli from a degenerated nucleus is possible; is, however, of infrequent occurrence, and the bacilli in the blood are usually overcome and rendered innocuous by the succeeding injections.

The present mode of applying Koch's remedy develops in the affected organism a diseased condition which is much more severe, and besides is fraught with many dangers. Improvement and respective cure of the

[1] Berlin klin. Wochenschr., 1890, No. 51, pp. 1182.

affected organs supervenes only after these artificially induced conditions no longer appear.

As we occasionally observe local reaction without general reaction, without a febrile movement, etc., we may ask whether it would not be advisable to begin the treatment with very minute doses; the organism becomes rapidly tolerant to the remedy, and after a time would also accommodate itself to larger doses without the symptoms of fever, etc. If it be possible to produce the same results with this mode of treatment, it is certainly much more preferable and less danger is connected therewith.

A detailed account of the picture presented to us in the course of the Koch treatment was unnecessary, especially as all of you have the opportunity to witness it yourselves at the various hospitals, and particularly at Mt. Sinai and German Hospitals, where our beloved president made the first injections. I have not looked to details in my paper, and it is written only for the purpose of eliciting discussion upon this important subject.

Before closing, however, I cannot abstain from reminding you that, in spite of all credit due to Koch, Pasteur, the father of modern bacteriology and the discoverer of the cure for rabies, should not be forgotten.

Now and to eternity do we and the whole world owe thanks to both Pasteur and Koch for the important discoveries they have presented to us.

120 East Sixty-fourth Street.

Progress of Medical Science.

Oxaluria.—Cantani states that an assemblage of nervous manifestations, of decidedly abnormal character, lasting for several years, may, under the influence of certain causes, undergo transformation more or less suddenly into a pathological state which is characterized by the appearance in the blood of oxalate of lime, and by the excretion of this salt in the urine. In these cases we have to do, not with an accumulation, the result of diet, but with an abnormal and continuous production of oxalic acid, at the expense of the tissues of the organism. We have here a quite particular individual predisposition, an alteration of the nervous system, and very likely of the cerebrum; the result of this affection of innervation is a retardation of nutrition, or, it may be, a qualitative abnormality in the transformation of the sugar circulating in the economy. The abuse of gaseous waters, and particularly of Seltzer waters, according to Cantani, has a great importance on the etiology of oxaluria. Heredity has also a considerable part, and Cantani's observations agree with those of Neidert, that diabetes may alternate with oxaluria, or coexist with it. Oxaluria is a disease *sui generis*, which, by itself and the accidents which it occasions, has a character of sufficient gravity to cause death. Considering our ignorance of the pathogeny of this affection, it is difficult to institute any rational therapeutics; but as the nervous and gastric troubles are the initial and essential symptoms, we should first combat these. The ingestion of easily digestible azotized aliments will enable one to guard against the evils of abnormal oxidation processes, and spare the nitrogenized tissues. Warm baths, with frictions and cold affusions during the bath, have rendered incontestable service against the nervous manifestations, and especially the trembling of the extremities, and the insomnia; Faradization has also given good results. Medicines of every kind have always failed; Cantani, nevertheless, recommends hydrochloric acid, pepsin, the carbonated alkalies, and especially, bicarbonate of soda and lithia. Neidert affirms that he has obtained the best results from a rigorous nitrogenous regimen similar to the diabetic regimen.—*The Boston Medical and Surgical Journal.*

Eczema from the Use of Creolin.—Cases have recently been reported in which more or less unfavorable results have followed the employment of creolin. In the majority of these cases the effects are attributable to the phenic acid and its derivatives in this proprietary remedy. Dr. Borehmeyer reports the case of a child, two and a half years of age, in which a severely-contused wound was treated by applications of a one and a half per cent. solution of creolin. On the fourth day the finger was covered with vesicles, both small and large, which ruptured spontaneously, giving issue to a yellowish liquid. The eruption soon disappeared from the injured hand, and, on the removal of the application, a cure was rapidly procured, though the eruption again returned on renewed application of creolin. So also Dr. Wackez publishes an account of seventeen different surgical cases treated by creolin. In ten of these union by first intention occurred; in seven the creolin produced eczema, erythema, and vesicular eruptions, and desquamation of the skin in large patches; at the same time the patients had more or less severe constitutional disturbance, and an examination of urine showed that these poisonous effects were attributable to the presence of phenol. It would seem, however, that children are especially susceptible to the deleterious effects of phenol and its derivatives, and hence are more readily influenced by creolin. —*Therepeutic Gazette.*

Tuberculosis Uro-genitalis.—Dr. J. P. Bryson (*Boston Medical and Surgical Journal*) says that: 1. The pathogenic factor reaches the parts involved by way of the hæmatic channels. 2. More than one part of the urogenital system is affected very early in the history of the disease, perhaps simultaneously. 3. The prostato vesical and periprostatic regions show by far the greater liability to early involvement. 4. All the evidence points to the conclusion that we have to deal, even in its earliest recognizable stages, with a general disease which manifests itself by localization. 5. Present experience does not warrant the belief that operations, however extensive, undertaken with the view of excising localized lesions and thereby radically curing the disease, will be successful. 6. Our chief resource is still in general anti tubercular treatment, reserving surgical interference for the palliation and relief of pain, bleeding, and wasting suppuration.

Salicylic Acid for Corns.—Dr. H. M. Whelpley, writing on the treatment of corns in *Notes on New Remedies* says that probably the most popular corn cures depend on the action of salicylic acid. Among the many therapeutic properties of this remedy is its power to disintegrate epithelial tissue. It is usually combined with cannabis indica. The form the writer has found useful is to mix nine parts of salicylic acid with one part of extract of cannabis indica and forty-eight parts of collodion. This is applied to the corn every night, with a camel's hair brush. The foot should be clean before it is applied, and the mixture permitted to thoroughly dry before it comes in contact with clothing. A salicylic acid corn plaster is made by melting six parts of resin, and adding five parts of balsam of fir, and then stirring in ten parts of salicylic acid as it cools. This can be spread on any suitable medium for a plaster. When used, the corn must not be rubbed with the shoe. Lanolin forms the basis of another salicylic acid plaster, and cocaine is added with the idea of making it painless. To form the plaster, mix six drachms of salicylic acid thoroughly with ten drachms of lanolin. Dissolve five grains of hydrochlorate of cocaine in a small quantity of warm alcohol and mix the solution with one fluid ounce of creasote. Mix one-half ounce of melted white wax with one half ounce of vaseline and add the creasote solution. To this add the cocaine solution and mix.

Quassia for Phtheiriasis.—Lice and other parasites are removed from the hair quicker and better by a decoction of quassia, to which a little borax and glycerine have been added, than by almost any other known means.—*Medical Brief.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, January 10, 1891.

THE ENZYMES AND KOCH'S DISCOVERY.

IT is well known that peptones are capable of producing toxic symptoms when injected into the current of the blood. Schmidt-Mühlheim appears to have been the first to call attention to this fact some ten years ago.

Béchamp and Baltus have also pointed out that various enzymes acted as powerful poisons when injected into veins. Dogs can be killed by relatively small doses of pancreatin and the diastase of malt. Diarrhœa and vomiting follow their intravenous use, and autopsies show congestion and hemorrhage of many organs. The enzymes reappear in the urine.

Drs. Nencki and Sahli have just published a preliminary communication on this subject in the *Correspondenzblatt für Schweizer Aerzte*, chiefly on account of the great interest excited by Koch's recent announcements regarding his lymph. The enzymes, or soluble ferments, belong to the group of proteid bodies known as toxalbumins. That the enzymes, like the peptones, are albuminoids, has been demonstrated by Loew (*Pflüger's Archiv*).

It can be now stated that every organism, no matter how minute, produces enzymes. Indeed, some of the lowest known organisms, as the algæ and schizomycetes, have of late had very powerful enzymes assigned to them. A few years ago Nencki published some observations (*Archiv für exper. Pathol. und Pharmacol.*, vol. xx.) in which he referred to the enzymes as follows: "The action of enzymes is due to the labile groups contained in each molecule. They are very unstable bodies. Acids, alkalies, metallic salts, and alcohol destroy their potency. Even keeping enzymes in a dry state at ordinary temperatures renders them liable to undergo radical changes. They often become insoluble or entirely inert under such circumstances. High temperatures are also inimical to enzymes."

Considerable discussion has taken place recently concerning the methods by which the animal body resists microbic invasion, more particularly in infectious diseases. The phagocytes of Metchnikoff are credited with much power in this direction. Healthy blood-serum has likewise been found to be possessed of bacteriocide properties. Now it is quite possible that just as the action of pathogenic bacteria on the human organism is very variable, so, too, the body may "react" in many different ways toward their presence. And it is further very probable that such "reactions" are brought about precisely by these changeable enzymes; that they, in fact, represent so many weapons employed by the body in its fight against infection.

In this connection it must appear strange that, under normal conditions, the enzymes and even the peptones of the alimentary canal do not enter the blood-current, or else do so only in very minute quantities. For the peptones it has been definitely ascertained that they are converted into true albumins within the mucous membrane of the digestive tract. Similar changes presumably occur in the enzymes.

Nencki offers the following theoretical consideration in explanation of certain well-known phenomena, which we may perhaps simply call the *vis medicatrix naturæ*: If certain organs of the body are threatened by invading microbes, the enzymes are called upon to avert the danger, or lessen its effects. To us such an arrangement would appear much like the telegraphic fire-alarm of modern cities. And the human organism, acting in an automatic manner, the inconvenience or danger of false alarms would seem to be obviated.

The authors suggest that the good effects observed after the inoculation of the organism of erysipelas in malignant neoplasms, may be entirely due to the production of potent enzymes by the cocci in question. Bouchard and others have certainly shown that the products of the metabolism of specific microbes confer immunity upon the body against infection from that particular organism.

Keeping these points in view, Nencki and Sahli have already undertaken inoculation experiments on human beings, after having made preliminary tests in animals. We are promised more information in subsequent communications. The statements now put forward have been prompted by Koch's publication, and the authors hint at the strong belief entertained by them that Koch's lymph belongs to the group of bodies known as enzymes, or soluble ferments.

Of course, where so little is actually known, one man's guess is as good as another's. Nevertheless, Nencki and Sahli have already become known through a number of faithfully conducted observations, so that we shall await with interest their further communications on this interesting subject.

ON THE ABUNDANCE OF MEDICAL LITERATURE.

DR. JAMES ANDREW, in his Harveian oration, delivered in October last, says these words:

"In the first rank of the ills which beset the profession I do not hesitate to place the enormous amount of so-called medical literature. Were it all good there would still be quite enough of it. But could we get rid of the vain repetitions of all those books which contain little or no original work, and are too often the damaged seed, not the fruit, of practice and of a ripe experience; could we get rid of all the clinical observations, with the idle theories based upon them, which from their imperfections are simply misleading; could this be done, the residue would, no doubt, be small."

While appreciating the feelings which animate the distinguished lecturer, we cannot go quite so far as he in his condemnation of current medical literature. It must be

remembered that medicine has to be entirely rewritten almost every decade. With the exception, perhaps, of anatomy and obstetrics, there is not a text-book published in the eighties which would be consulted or studied systematically now, unless thoroughly revised. Then, again, there is constantly a new influx of young medical men, to whom much that to older physicians seems commonplace and valueless has a decided use.

The speaker's remarks about a certain much-esteemed bibliographical monthly will awaken feelings of genuine horror among those who have been self sacrificingly contributing to its support. He says:

"There is one publication which I regard with especial horror, the 'invaluable' *Index Medicus*. I find that the volume for 1889, the last completed but not the greatest of eleven volumes, contains the names of not less than 13,870 contributors. Now, the index of the *Index* fully bears out the supposition that each pair of contributors represents not less than three communications, and thus we have a total of not less than 20,000 contributions to medical science for last year. I have much pleasure in admitting that many of them are short; but then it must not be overlooked that very many of them are substantial treatises in two volumes or more."

The trouble with the *Index* is not its bulk, however, but the fact that it is ingeniously arranged and published, so as to be relatively valueless to those who wish to consult it, and have not indefinite leisure for so doing.

The quotation from Harvey given by Dr. Andrew bearing upon the subject in hand is doubtless true and is certainly most interesting and pertinent. "I venture to think," says Dr. Andrew, "that no small part of medical literature would never have been written had its authors given heed to Harvey's words at the end of the dedication of his treatise on the 'Motion of the Heart and Blood.' 'My dear colleagues,' he writes, 'I had no purpose to swell this treatise into a large volume by quoting the names and writings of anatomists, or to make a parade of the strength of my memory, the extent of my reading, and the amount of my pains; because I profess both to learn and to teach anatomy, not from books but from dissections; not from the positions of philosophers but from the fabric of nature. I avow myself the partisan of truth alone; and I can indeed say that I have used all my endeavors, bestowed all my pains in an attempt to produce something that should be agreeable to the good, profitable to the learned, and useful to letters.'"

Let our medical authors, young and old, bear these words ever in their memory.

PROGRESS OF THE KOCH TREATMENT ABROAD.

Reports of clinical tests with Koch's lymph continue to occupy much space in our foreign exchanges.

Gerhardt states that apparently tuberculosis of the larynx is more amenable to treatment by lymph than ordinary tuberculosis of the lungs.

Leyden says that, on the whole, the diagnostic value of the remedy can be accepted. Nevertheless, it is not absolute. He has found non tubercular patients developing reaction, and also tubercular patients without it. He is also of opinion that the prognosis of cases subjected to lymph treatment cannot be positively stated from the manner of their reaction. We cannot as yet say that a strong reaction means much tubercular tissue and a mild one only a little of it. Nor is he willing to proclaim a patient as cured when reactions have ceased. As regards ordinary phthisis, the well-advanced cases were not at all benefited by the treatment. In the earlier stages some patients did well and others were very much improved. He would regard a patient as cured only if he remains free from relapses for several years. It is to be remembered that the early stage of phthisis is amenable to treatment by ordinary methods hitherto employed, and that it is precisely in this stage that the lymph treatment has given its most promising results. Finally, he says that it would be wrong to neglect older methods and employ the Koch treatment exclusively. He agrees with Fraentzel in the statement that the lymph leads to such extraordinary manifestations that every day new impressions of its power and manifold action are received. It is to be hoped that the lymph may yet turn out to be a true specific for tuberculosis.

Ewald, Henoch, Litten, Helferich, Hofmeier, Kast, Rydygier, Cornil, Heron, Watson, Cheyne, and many others have published their observations, and the general consensus of opinion seems to be to the effect that the diagnostic significance of the lymph is no longer doubtful.

Professor Sonnenburg is using surgical measures in dealing with cavities in the lungs.

Ewald records the rapid absorption of pleuritic effusion under lymph treatment. He has not yet found objective signs pointing to as radical changes in the anatomical condition of the lungs in phthisis.

Jarisch has published a case under treatment for lupus vulgaris in which death occurred thirty-six hours after the injection of 0.002 gm. of lymph. At the autopsy congestive swelling of all tubercular deposits, including tracheal and bronchial glands, was the most obvious condition found. In the lungs disseminated pneumonic infiltrations and œdema were seen. Brain and spinal cord markedly œdematous. Enlargement of the spleen, and slight tumefaction of the liver and kidneys were also noticed. Capillary hemorrhages were observed into the pleura, the pericardium, the thymus gland, and the spinal cord.

Hofmeier has found Koch's lymph to be well borne by two pregnant women.

Burkart (*Berliner klinische Wochenschrift*, December 22, 1890) states, as the result of his experience, that Koch's lymph must be employed with the utmost caution, or not at all, in advanced phthisis. In all consumptives, asphyxia, due to unsuspected laryngeal tuberculosis, and intestinal perforation, due to necrosis, are to be thought of as possible accidents.

Professor v. Ziemssen (*Münchener Medicinische Wochenschrift*, December 16, 1890) is more favorably impressed with the curative properties of the lymph than some of his German confrères. He has had one hundred and forty cases under observation. Hyperæmia of the conjunctiva palpebrarum was often noticed. The spleen was frequently found enlarged. The weight of the body diminishes, probably on account of the febrile re-

actions. No perceptible effect on the number of bacilli in the sputum could be found. Cough, at first increased, later diminishes so that narcotics can be discontinued.

From Switzerland it is reported that the number of consumptive patients now undergoing Koch's treatment at Davos exceeds five hundred. In none of the cases have any alarming symptoms been observed, while in many patients a ten to fourteen days' course of the injection is said to have had highly encouraging and in some even "very striking" results, which could have been obtained only by several months' treatment according to the old-fashioned methods formerly practised at the Alpine health resort. It is added that the amelioration was observed even in cases of a decidedly severe nature.

The cases reported from England show about the same results that have been witnessed elsewhere.

In Spain the lymph was given to two lepers. One fatal issue is said to have resulted from inoculations in the case of a girl.

It is announced that a sanatorium designed expressly for the carrying out of Koch's treatment will shortly be opened at Nervi by Dr. Launien.

Dr. Angerer, Director of the Munich Surgical Clinic, is much encouraged by his results in surgical cases. He warns against rash employment of the fluid, on account of latent or unsuspected internal tuberculosis in external surgical affections of the same nature.

Dr. Schede, Surgeon-in-chief of the Hamburg Hospital, expresses his opinion to the effect that surgical measures will remain indispensable in dealing with accessible tubercular manifestations, such as white swelling and the like. He does not believe it at all justifiable to employ the lymph in marasmic or otherwise enfeebled patients. The constitutional "revolution" engendered by Koch's lymph is dangerous in that class of sufferers.

Professor v. Jaksch, of Prague, observes that the elective affinity of the lymph for tubercular tissue is now abundantly established.

Czerny, of Heidelberg, believes that advanced cases of phthisis can only be injured, instead of being benefited by the lymph. He has seen, in surgical cases, violent local reaction without constitutional symptoms, and also the opposite phenomena, of general symptoms without appreciable local change.

Ebstein, of Göttingen, sees a contra-indication for the use of lymph in the presence of intestinal or peritoneal tuberculosis, on account of the great danger of sloughs, leading to perforation.

Virchow says the lymph is dangerous in children and very old people. But he believes it may be possible to effect a cure in the very earliest stages of phthisis.

THE STATE HEALTH BOARD.

In his annual message to the Legislature Governor Hill recommends the abolition of the State Board of Charities and State Board of Health. In their place he advises the appointment of a single man, upon whom responsibility and executive work would be concentrated.

We hardly see the need or wisdom of such a change. Heretofore, in all parts of the world sanitary work has been done through the agency of Boards or Commissions. There is necessarily always one member who is the executive officer, and on whom the responsibility mainly falls. But this officer has the advantage of being able to obtain advice and support from his colleagues. The Board system has worked well; the single officer system is an experiment, and we can find no good reason for attempting it.

In the case of the Lunacy Commission of this State, it is well known that while there was but one Commissioner there were constant complaints, and relatively little progress in lunacy reforms. Since the establishment of a triple Commission, a great deal more has been done both in securing new legislation and in carrying out effectively existing laws.

News of the Week.

A Good "Annus Medicus."—The articles put forth at the beginning of each year under the head of "Annus medicus" are ordinarily rather juiceless and uninteresting reading, but our Yankee contemporary, the *Boston Medical and Surgical Journal*, publishes this year an "Annus" that is concise, complete, and worthy of attentive perusal.

Italian Quacks and the Lymph.—The *Basler Nachrichten's* special Italian correspondent, writing from Milan, states that Koch's discovery is there degraded in a highly disgraceful manner. Circulars are sent round by obscure doctors, announcing that they have just received a sufficient supply of Koch's lymph, with which they are prepared to cure consumptive patients. The lymph is in no case genuine, and yet phthisical patients, of whom there are many in Milan, flock to fill the coffers of those medical *chevaliers d'industrie*. The authorities have as yet taken no step to prevent or punish this abuse. The following is a translation of the inscription on the signboard of a "dispensary:" "Teeth extracted, corns cut, and tuberculosis cured after Professor Koch's method."—*British Medical Journal*, December 27, 1890.

Chromatic Antiseptics.—Before the recent introduction of aniline colors as antiseptics, one could often tell by their various odors what antiseptic substances a surgeon preferred; but now the hues that adorn his hands give him away. Steady elderly gentlemen may be content with a monochromatic dressing; while younger men, of more æsthetic tastes, will prefer substances more cunningly mingled, so as to produce the general effect of the patch-work quilt of our aunts and the coat of Joseph.—*Boston Medical and Surgical Journal.*

A Hospital Historical Club has been organized at the Johns Hopkins Hospital, for the purpose of studying medical history. Dr. Welch was elected president. Dr. Kelly proposed for the society the motto "Il importe beaucoup de connoître l'histoire de la science à laquelle on s'attache." (Éloge Critique de Boerhaave, taken from the titlepage of the "Dictionnaire Historique de la Médecine," Eloy, Mons, 1778.) He presented a curious American book on "Primitive Physic; or, an Easy and Natural Method of Curing most Diseases," by John Wesley, the Father of Methodism; 125 pp., printed at Trenton, New Jersey, by Quequelle and Wilson, 1788.

Another Claimant for a Curative Lymph. — Dr. Joseph Craft, of Cleveland, announces that he also has a "curative lymph" which resembles Koch's, in this respect at least, that its formula is not given. Dr. Craft states that he is "a healthy young man," and we would add a modest one. An injection of the lymph caused a rise of temperature in himself, but he does not seem to have gone further than this in his experimentation, unless it be the brief statement that he has "put it to the crucial test on rabbits and guinea-pigs." It is not creditable to American science or sense that, upon such absolutely baseless foundations, assertions regarding a curative lymph should be seriously received. The very fact that it causes a fever in "a healthy young man," shows that it is not in any way like the Koch fluid.

Professor Frank Baker, the well-known anatomist, has been appointed Curator of Comparative Anatomy at the Smithsonian Institution, and *ex-officio* Superintendent of the National Zoological Park. It is gratifying to learn of the appointment of a competent anatomist to a position of this kind.

A Well-equipped Hospital exists at Greytown, Nicaragua, having a capacity of one hundred and twenty-five beds. Dr. J. Edward Hubbert is the surgeon in charge. It belongs to the Canal Company and is for the benefit of its employees. The material largely used in the construction of the hospital buildings—twelve in number—is corrugated iron, thus obviating in part the dangers of fire and infection. The wards are said to be furnished throughout with all the appliances that are found necessary in the best-regulated hospitals of New York, while, thanks to the mild climate, measures for ventilation have been available that could not be employed in colder climes. A corps of trained nurses has been taken down, also a competent pharmacist with a liberal provision of drugs.—*New York Medical Journal.*

Medical Prizes in Paris.—The Académie de Médecine, of Paris, has twenty-eight annual prizes to award, varying in amount from $50 to $5,000. In the past year one hundred and seven essays were received in competition, or an average of about four for each prize. In eighteen cases the prizes were awarded; in ten, no essay of sufficient merit was received.

A Fat Men's Congress was recently held at Berlin, and the following data were collected: Herr Berg, a brewer, from Sraulau, was the largest man, weighing 399 pounds, or upward of 28 stone; Ferdinand Colin, from Angemunde, another delegate, weighing 365 pounds; and Herr Hubert, a saloon keeper of Berlin, weighing 364 pounds.

Dr. Gideon B. Perry, one of the oldest practitioners in Brooklyn, died on December 30th from heart trouble. Dr. Perry was born in Hopkinton, R. I., in 1826, and was graduated from the University of the City of New York in 1851.

Northwestern Medical and Surgical Society of New York.—On p. 731, issue of MEDICAL RECORD, December 27th, a news item, headed "Northwestern Dispensary," should be Northwestern Medical and Surgical Society, as it states the election of said society, and has nought to do with the Dispensary.

The American Association for the Study and Cure of Inebriety is now holding a series of monthly meetings at the Academy of Medicine in this city.

Professor Bartholow's Successor.—The trustees of Jefferson Medical College have elected Dr. A. P. Brubaker as the successor to Professor Bartholow in the Chair of Materia Medica and General Therapeutics.

Elizabeth, not Emily.—Dr. Emily Blackwell, of this city, writes: Will you kindly correct an error in the letter of Dr. Stephen Smith on the "Co-education of the Sexes," printed in your last number. The error is in the name of the student referred to. The name should be Dr. Elizabeth Blackwell. It was my sister Dr. Elizabeth Blackwell who studied at Geneva, and it is to her that the article refers.

The Proposed Italian Hospital.—Dr. G. W. Kirch, of this city, writes: In the issue of December 27th of the MEDICAL RECORD, in an article on the Italian Hospital to be founded in this city, you express the opinion whether hired interpreters for the various existing city hospitals could not accomplish a charitable work for very much less money than would be required for a new hospital. The language is not the only difficulty for the poor Italians to be made comfortable in the city hospitals. The question of food and nourishment is far more important, and Italians are accustomed to such a different diet from Americans that, particularly when they are ill, they want food prepared as is customary in their own country. There are many other obvious reasons for which an Italian hospital is needed and which would be too long to enumerate. I hope and feel certain that you will use your valuable influence to assure the success of the Italian Hospital in this city.

The New Jersey Sanitary Association held its sixteenth annual meeting at Trenton, on Friday and Saturday, December 12th and 13th. Ten papers and addresses were read.

"The Jolly Bacillus."—A coffee-house, with pretty waitresses, has opened in Berlin, bearing over its portals a sign consisting of Koch's portrait, with the inscription, "The Jolly Bacillus."

Medical Legislation in Nebraska.—A bill for an act to establish a State Board of Health and Medical Examiners, and to regulate the practice of medicine, surgery, and obstetrics in the State of Nebraska, has been prepared and will be brought before the Legislature.

Professor Nicholas Senn has resigned the professorship of Surgery and Surgical Pathology of Rush Medical College, Chicago. The resignation has been accepted.

A Brooklyn Post-Graduate Medical College.—According to the *New York Medical Journal*, articles of incorporation have been filed in Brooklyn as a first step toward the establishment of a post-graduate hospital and school in that city. The management of the institution will be vested in a board of medical councillors, among whom are Dr. Charles Jewett, Dr. Fowler, Dr. Jeffrey, Dr. Evans, and Dr. Butler. The aim of the faculty will be to cover every field of study in surgery and practical medicine. An outdoor department is included in the future scope of the enterprise.

There are Six Thousand Applications for the Koch lymph on file in Berlin.

Medical Journalism in Berlin.—The *Berliner klinische Wochenschrift* publishes two editions weekly in order to satisfy the demand for news about the "lymph."

If Koch's Lymph is scarce at Berlin, it is abundant at Davos Platz, where the arrival of some twenty five phials was announced a few days since, being enough to treat a thousand patients for a couple of months! There are 1,400 cases at Davos.

The United States Government and the Curative Lymph.—The Hon. Mr. Platt, M.C., of Connecticut, has introduced a resolution to appropriate $10,000 to enable the President to take action to obtain from the German Government a supply of the remedy discovered by Dr. Koch, and the formula for its manufacture.

The Librarian of the New York Hospital.—On January 1st the librarian, Dr. John L. Vandervoort, retired from the office of which he has discharged the duties almost continuously since 1837. At the time of his appointment the library consisted of only 4,166 volumes. Since then over 14,000 volumes have been added. Those who have had occasion to use the library in question will greatly miss the presence of the courteous and venerable librarian. The duties will be assumed by his son.

A Convention of American Physicians interested in electro-therapeutics has been called to meet at the Academy of Medicine, No. 17 West 43d Street, New York, on January 22, 1891, at 11 A.M., for the purpose of organizing an American Electro-therapeutic Association. The committee in charge consists of Drs. G. Belton Massey, A. H. Goelet, and H. R. Bigelow.

Reported Death of Professor Weigert.—The report of Professor Weigert's death, which was published in the German papers, is incorrect. He has been suffering very severely from a post-mortem wound, but he is now recovering.

The Paris Municipal Council and Koch's Method.—At one of the last sittings of this body a member proposed the following resolution: "The Council invites the authorities to prohibit in our hospitals any experiments being carried on with a substance the composition of which is unknown." This resolution was rejected by the substantial majority of 47 to 7, which says much for the good sense of the municipal council; for, considering its pronounced political feeling and international prejudices, it might have been credited with acting otherwise when it is borne in mind from what quarter the "unknown" emanates.

The Time of Day for Operating.—In this country most operations are done in the afternoon. The introduction of electric light has made it possible to operate until late in the day if needed. In Europe the practice of operating in the morning is common. The *British Medical Journal*, discussing this subject, says: "There is considerable difference of opinion among surgeons, as to whether it is best to operate early in the morning or in the afternoon. Many prefer the morning. They say that the patient is saved the suspense of being kept waiting till the afternoon, and the surgeon has the better chance of a good supply of sunlight or of its equivalent in this country. Both these reasons have considerable force. Other surgeons maintain that early operating implies a sleepless previous night. The shades of evening, a greater promoter of sleep than blinds and screens, come on sooner when the operation is performed in the afternoon. This physical fact also implies greater chances of rest in another respect, for there is less fear of subsequent disturbance from noises inside or outside the house when the surgeon operates late. Long operations may seriously tax the surgeon's strength and nerve, and in this respect again the afternoon is better for operating than the morning. In private practice, and wherever freedom from noise and plenty of warmth can be insured, the morning is probably the best time, especially in summer."

Men who are Working with Koch.—Professor Karl Fraenkel, whose highly important experiments with a view to conferring immunity against diphtheria, are now one of the chief topics of discussion in the medical world, is a pupil of Robert Koch. He passed his final examination as a physician in 1885, was appointed assistant in the Hygienic Institute on its establishment, and soon became Koch's first assistant there. In 1887 he established himself as private lecturer in Berlin University. About a year ago he was appointed professor of hygiene at Königsberg. He became generally known in medical circles by the publication of his "Elements of Bacteriology," in 1886. This book recently appeared in a third edition, and has the reputation of being the best of its kind. The most important of Fraenkel's special investigations are those of bacterial poisons, which he made in common with Ludwig Brieger. They led to the discovery of toxalbumin, and to that above mentioned. His other discoveries are those concerning the bacterial contents of ice, the cultivation of bacteria which thrive without air, the occurrence of micro-organisms in the various layers of the soil, etc. Dr. Kitasato, a Japanese by birth, has lived in Germany, for five years, and has occupied himself almost all the time with bacteriological studies in the Hygienic Institute here. The biology of the cholera bacillus has been the theme of many of his researches. He has investigated its behavior in milk and in fæces, and its relations to other pathogenic and non-pathogenic bacteria in nutritive solutions. He has also gone deeply into the study of the tetanus germs, and has now published the results of his investigations in his article on immunity. One of his chief discoveries is that of the musk fungus. Dr. Ernst Behring, who has shown, in conjunction with Dr. Kitasato, how immunity against diphtheria and tetanus is conferred on animals, is an army surgeon, and has been working as an assistant for about a year and a half past in the Hygienic Institute here. Among his first studies after he became a surgeon, ten years ago, was the manner in which antiseptic remedies for wounds, especially iodoform, act, and he made a special study of the symptoms of iodoform poisoning. He afterward tested the antiseptic value of silver solutions, creoline, and other chemicals. Cadaverine, the etiology of anthrax, and the immunity of rats are also among the themes to which he has devoted special attention, but diphtheria has recently been his exclusive study.—*The Lancet.*

THE KOCH TREATMENT IN NEW YORK.

CASES AT ST. MARK'S HOSPITAL.

Service of DRS. L. WEBER and GEORGE W. RACHEL.

(Reported by DR. KAHN, House Physician.)

Report of old and new patients treated at the St. Mark's Hospital, from December 22, 1890, to January 6, 1891.

Old Cases.

CASE I. *Phthisis.*—William P——. December 23, 1890. 9 A.M.: Temperature, 98.2° F.; 5 P.M.: Injection of 0.002 milligr.; 11 P.M.: Temperature, 100.4° F.

December 24th. 9 A.M.: Temperature, 98.2° F.; 3 P.M.: Slight chill; 4 P.M.: injection of 0.002 milligr.; 10 P.M.: Temperature, 100.2° F.

December 25th. 9 A.M.: Temperature, 98.2° F.; 4 P.M.: injection of 0.002 milligr.; 5 P.M.: Temperature, 101° F.

December 26th. 9 A.M.: Temperature, 98.2° F.; 7 P.M.: Temperature, 101° F.

December 27th. 7 A.M.: Temperature, 101° F.; 5 P.M.: injection of 0.002 milligr.

December 28th. 5 A.M.: Temperature, 97.6° F.; 7 P.M.: Temperature, 101° F.

December 29th. 9 A.M.: Temperature, 98.2° F.; 5 P.M.: Temperature, 101° F.; injection of 0.002 milligr.

December 30th. 9 A.M.: Temperature, 98.2° F.; 7 P.M.: Temperature, 101.2° F.

December 31st. 9 A.M.: Temperature, 97.3° F.; 5 P.M.: Temperature, 101.1° F.; injection of 0.002 milligr.

January 1, 1891. 7 P.M.: Temperature, 101.2° F.

January 2d. 7 P.M.: Temperature, 101.4° F.

January 3d. 9 A.M.: Temperature, 98.3° F.; 5 P.M.: Injection of 0.003 milligr.

January 4th. 9 A.M.: Temperature, 101° F.

January 5th. 9 A.M.: Temperature, 97.4° F. Sputum shows no appreciable difference in number of bacilli, but most of them are smaller and their outlines not as straight as at first examination.

CASE II. *Phthisis.*—Samuel S——. December 23, 1890. 5 P.M.: Temperature, 99° F.; injection of 0.002 milligr.

December 24th. 9 A.M.: Temperature, 98.2° F.

December 25th. 9 A.M.: Temperature, 98° F. Complains of increased cough, but very dry and troublesome; slept much better than before, and feels excellent; 4 P.M.: injection of 0.002 milligr.

December 26th. 9 A.M.: Temperature, 98.4° F. Had seven hours' sleep; feels first-rate; cough and expectoration easier.

December 27th. 9 A.M.: Temperature, 98.2° F.; 5 P.M.: Injection of 0.002 milligr.

December 28th. 9 A.M.: Temperature, 99° F.; 7 P.M.: Temperature, 102° F.

December 29th. 7 A.M.: Temperature, 98.2° F.; 5 P.M.: Injection of 0.002 milligr.

December 30th. 9 A.M.: Temperature, 98° F. Slept poorly; coughed more; expectoration easier.

December 31st. 9 A.M.: Temperature, 98.1° F. Expectoration very copious; 5 P.M.: Injection of 0.002 milligr.

January 3, 1891. 3 P.M.: Temperature, 99.2° F.; injection of 0.002 milligr.

January 4th. 9 A.M.: Temperature, 98.2° F.

January 5th. 11 A.M.: Temperature, 98.2° F.

CASE III. *Phthisis Pulmonalis Tuberculosa, First Stage.*—Marcus A——. December 23, 1890. 9 A.M.: Temperature, 98.2° F.

December 25th. 9 A.M.: Temperature, 98.4° F.; 5 P.M.: Injection of 0.006 milligr.; 11 P.M.: Temperature, 98.2° F. Temperature was normal for December 26th, 27th, 28th, 29th, and 30th.

December 31st. 9 A.M.: Temperature, 98.4° F.; 5 P.M.: Injection of 0.01 milligr.

January 1, 1891. 1 A.M.: Temperature, 103° F.; 9 A.M.: Temperature, 100.3° F.; 9 P.M.: Temperature, 101.8° F.

January 2d. 9 A.M.: Temperature, 98° F.

January 3d and 4th. Temperature normal.

January 5th. 5 A.M.: Temperature, 97.4° F.; 9 A.M.: Temperature, 98.4° F.; 9 P.M.: Temperature, 98.2° F.

CASE IV. *Phthisis.*—Emma K— . December 22, 1890. 4.30 P.M.: Temperature, 99.8° F.; injection of 0.002 milligr.; 11 P.M.: Temperature, 99.6° F.

December 23d. 9 A.M.: Temperature, 100° F.; slept well during night and feels excellent; 5 P.M.: Temperature, 100.4° F.; injection of 0.002 milligr.

December 24th. 9 A.M.: Temperature, 99.4° F.

December 25th. 8 A.M.: Temperature, 99.2° F.; 4 P.M.: Temperature, 100.8° F.; injection of 0.002 milligr.

December 26th. 9 A.M.: Temperature, 99.4° F.

December 27th. 8 A.M.: Temperature, 98.4° F.; 5 P.M.: Temperature, 101.4° F.; injection of 0.002 milligr.

December 28th. 9 A.M.: Temperature, 99° F.

December 29th. 8 A.M.: Temperature, 99° F.; 5 P.M.: Temperature, 99.6° F.; injection of 0.002 milligr.

December 30th. 9 A.M.: Temperature, 100.8° F.

December 31st. 9 A.M.: Temperature, 99.2° F.; 5 P.M.: Temperature, 99.4° F.; injection of 0.004 milligr.; 10 P.M.: Temperature, 102.6° F.

January 1, 1891. 10 A.M.: Temperature, 99.8° F.

January 2d. 9 A.M.: Temperature, 99° F.

January 3d. 5 P.M.: Temperature, 100.6° F.; injection of 0.004 milligr.

January 4th. 1 A.M.: Temperature, 99° F.

January 5th. 9 A.M.: Temperature, 99.4° F.; 5 P.M.: Temperature, 100° F.; injection of 0.004 milligr.

CASE V. *Phthisis.*—Emma R——. December 22, 1890. 4 P.M.: Temperature, 102.8° F.; injection of 0.002 milligr.; 11 P.M.: Temperature, 100.8° F.

December 23d. 9 A.M.: Temperature, 100.6° F.; 7 P.M.: Temperature, 101.8° F.; injection of 0.002 milligr.

December 24th. 9 A.M.: Temperature, 100° F.; slight chill.

December 25th. 4 P.M.: Temperature, 102.6° F.; injection of 0.002 milligr.

December 26th. 9 A.M.: Temperature, 101.6° F.

December 27th. 9 A.M.: Temperature, 100° F.; 5 P.M.: Temperature, 102.8° F.; injection of 0.003 milligr.

December 28th. 12 M.: Temperature, 101° F.; slight chill.

December 29th. 9 A.M.: Temperature, 102.2° F.; 5 P.M.: Temperature, 101.4° F.; injection of 0.003 milligr.

December 30th. 9 A.M.: Temperature, 100° F.

December 31st. 9 A.M.: Temperature, 100.4° F.; 5 P.M.: Temperature, 102° F.; injection of 0.003 milligr.

January 1, 1891. 9 A.M.: Temperature, 99° F.

January 3d. 9 A.M.: Temperature, 101.2° F.; 5 P.M.: Temperature, 102° F.; injection of 0.003 milligr.

January 4th. 8 A.M.: Temperature, 99° F.

January 5th. 9 A.M.: Temperature, 99.2° F.; 5 P.M.: Temperature, 100.8° F.; injection of 0.003 milligr.; patient appeared to be quite weak, and it is thought prudent to interrupt treatment for the present.

CASE VI. *Phthisis.*—B. G——, reinoculated January 3, 1891. 4 P.M.: Temperature, 98.3° F.

January 3d. 5 P.M.: Injection of 0.004 milligr.; 11 P.M.: Temperature, 102.8° F.; chill.

January 4th. 1 A.M.: Temperature, 103° F.; perspiration several hours. 9 A.M.: Temperature, 100° F.

January 5th. 9 A.M.: Temperature, 99° F.

CASE VIII. *Phthisis.*—John G——, December 22, 1890. 4 P.M.: Temperature, 98.4° F.; injection of 0.001 milligr.; 11 P.M.: Temperature, 99.4° F.

December 23d. 9 A.M.: Temperature, 100.2° F. Nausea during whole of night. Headache, and complains of dry heat all over body, as if he was burning up inside; 5 P.M.: Injection of 0.012 milligr.

December 24th. 9 A.M.: Temperature, 100.1° F.; 7 P.M.: Temperature, 99° F.

December 25th. 9 A.M.: Temperature, 98.2° F.; slept well during the night; first good night's sleep without assistance (narcotics) in two years, and feels very much better; 4 P.M.: Temperature, 98.4° F.; injection of 0.002 milligr.

December 26th. 9 P.M.: Temperature, 99.2° F.

December 27th. 5 P.M.: Injection of 0.002 milligr.

December 28th. 11 P.M.: Temperature, 97.3° F. Severe attack of dyspnœa.

December 29th. 9 A.M.: Temperature, 98° F. Slept well during night; cough and expectoration easy; does not cough as much as before; 5 P.M.: Injection of 0.002 milligr.

December 31st. 9 A.M.: Temperature, 98° F.; 5 P.M.: Injection of 0.002 milligr.

January 3, 1891. 5 P.M.: Injection of 0.003 milligr.

January 4th. 9 A.M.: Temperature, 98.2° F. Chills and fever, insomnia, and great pain in chest and back all night.

January 5th. 9 A.M.: Temperature, 99° F.

New Cases.

CASE IX. *Lupus Vulgaris.*—Margareta Z——, aged forty-six; married, healthy, strong; lupus vulgaris of right side of face since her fourteenth year. Nodules can be distinctly seen and felt all along periphery. A very characteristic case of lupus.

December 27, 1890. 5 P.M.: Injection of 0.003 milligr.; 10 P.M.: Temperature, 98.8° F.; pulse, 88; no chill.

December 28th, at 2 A.M., general symptoms, heat, nausea, headache, backache, and painful or tired feelings in limbs. Facial lupus swollen, red, and hot. 8 A.M.: Temperature, 99.2° F.; pulse, 94; 1 P.M.: Temperature, 100.2° F.; pulse, 104. Entire lupus surface and 0.5 inch beyond it, red with bluish tinge, hot, elevated, slightly tender, but not painful to pressure of finger; lupous nodules not more prominent, whitish in color (the entire part presenting an erysipelas-like appearance), two submaxillary lymph-glands somewhat enlarged; 11 P.M.: Temperature, 99° F.; pulse, 90.

December 29th. 10 A.M.: Temperature, 98.6° F.; pulse, 80. Passed a comparatively good night. Pulse weak, some nausea, no appetite, feels very tired but is able to be about. Swelling, redness, and elevation of parts somewhat diminished. Heat also much less.

December 30th. Pulse and temperature rather normal, feels generally uncomfortable and weak, no appetite. Local condition about the same as yesterday. More tension along inner, lower, and outer circumference of lupus; crusts and scales forming. No appetite.

December 31st. Same as yesterday. Sensations of trembling, no fever.

January 1, 1891. Appetite returning, general condition improved. Locally, tension greater, crusts thicker, and adhering closely to skin, which still maintains its erysipelatous appearance. No fever.

January 2d. Local condition same as yesterday; no signs of suppuration to be seen, but crust formation goes on as before. Pulse still feels shaky somewhat, but has fair appetite, bowels regular. No fever.

January 3d, 4th, and 5th. Gaining generally, pulse getting strong, many small crusts and scales falling off. Affected part still quite hard and stiff.

CASE X. *Phthisis Tuberculosa, Second Stage.*—Oscar D——, aged twenty-three, married; born in United States; father died, aged forty-five, of phthisis; mother died, aged thirty-eight, of pneumonia; two brothers and one sister living; never had rheumatism. Present illness dates back about two years, when patient first had a cough and slight expectoration; has lost weight since time of first attack.

December 25, 1890. Temperature, 101° F.; pulse, 96. Appetite not very good; bowels regular; features pale and emaciated.

December 26th. 1 P.M.: Temperature, 100.4° F.; injection of 0.001 milligr.; 7 P.M.: Temperature, 102° F.

December 27th. 9 A.M.: Temperature, 98.2° F.; 5 P.M.: Temperature, 102.2° F.; injection of 0.002 milligr.

December 28th. 9 A.M.: Temperature, 98.4° F.

December 29th. 9 A.M.: Temperature, 99.2° F.; 5 P.M.: Temperature, 103.2° F.; injection of 0.003 milligr.

December 30th. 9 A.M.: Temperature, 99° F.

December 31st. 3 P.M.: Temperature, 102° F.; at 5 P.M.: Injection of 0.003 milligr.

January 3, 1891. 9 A.M.: Temperature, 99° F.; 5 P.M.: Temperature, 102° F.; injection of 0.003 milligr.

December 5th. 9 A.M.: Temperature, 101° F.; 4 P.M.: Temperature, 100° F.; injection of 0.003 milligr.

This has been the first case of tubercular ulcer of right upper part of larynx, complicating pulmonary phthisis, treated by injections of the lymph at this hospital. When the patient entered, the ulcer, with congestion of epiglottis, pain, and difficulty in swallowing, etc., could be plainly observed. There was no local change after first injection, but twelve hours after the second increased cough, hoarseness, expectoration, edges of ulcer showing some elevation. Fortunately no symptoms of stenosis of larynx took place. After third injection, on the sixth day of treatment, ulcers begin to look clean, and there is marked amelioration of all above symptoms.

January 5th, improvement in larynx going on, posterior wall of pharynx showing an area of dark-red congestion and swelling which appears to annoy the patient in swallowing.

It is to be noted that the lymph has shown its energetic influence in laryngeal tubercular ulceration, though there is advanced pulmonary phthisis also present. Thus far there is no appreciable change in the condition of the patient's lungs, but he is able to be up and walks about the ward, which he could not do when he came in.

CASE XI. *Phthisis Tuberculosa.*—Charles S——, aged thirty-eight, married; piano-maker; born in Germany; father died aged seventy, cause unknown; mother died aged forty, some female trouble; one brother and one sister living. Present illness dates from December, 1889, when patient had the grippe. Says he has been unable to get rid of a cough which he had at that time.

December 27, 1890. 5 P.M.: Temperature, 100° F.; injection of 0.001 milligr.; 11 P.M.: Temperature, 99.2° F.

December 28th. 9 A.M.: Temperature, 99° F.; expectoration easier; 5 P.M.: Temperature, 101° F.

December 29th. 9 A.M.: Temperature, 98° F.; 5 P.M.: Temperature, 101° F.; injection of 0.002 milligr.

December 30th. 5 P.M.: Temperature, 99° F.

December 31st. 5 P.M.: Temperature, 101.2° F.; injection of 0.003 milligr.

January 1, 1891. 9 A.M.: Temperature, 99° F.; 7 P.M.: Temperature, 101° F.

January 2d. 5 P.M.: Temperature, 101.2° F.

January 3d. 9 A.M.: Temperature, 97.6° F.; 5 P.M.: Temperature 100.1° F.; injection of 0.003 milligr.

January 4th. 9 A.M.: Temperature, 100.8° F.

This case is one of tubercular phthisis in its first stage, the bacilli found in sputum being small and few in number. Unfortunately, the patient had to leave the hospital after the fourth injection, but he reported January 6th for examination to Dr. L. Weber, who has known him for some months, and who recognized a decided improvement in his local and general condition.

CASE XII. *Phthisis Tuberculosa, Second Stage.*—Adolph S——, aged fifty five; optician; married; born in Germany; father died, aged eighty-four, cause unknown; mother died, aged sixty, cause unknown; seven sisters and one brother all living. Has never had rheumatism; had pneumonia in 1877. Present illness dates back about eight years, when it commenced with slight spitting of blood and cough, also night-sweats, which did not last long. Has only had night-sweats at intervals. At pres-

ent has no night-sweats; has lost ten pounds in a year. Temperature, 98.2° F.; pulse, 101. Appetite capricious.

December 29, 1890. 5 P.M.: Temperature, 99° F.; injection of 0.002 milligr.

December 30th. 9 A.M.: Temperature, 98.2° F.; 5 P.M.: 98.2° F.; injection of 0.002 milligr.

December 31st. 9 A.M.: Temperature, 97.4° F.

January 3, 1891. 9 A.M.: Temperature, 98° F.; 5 P.M.: Temperature, 98.3° F.; injection of 0.002 milligr.

January 4th. 9 A.M.: Temperature, 97.4° F.

January 5th. 9 A.M.: Temperature, 98° F.; 4 P.M.: Temperature. 99° F.; injection of 0.002 milligr.

CASE XIII. *Phthisis Tuberculosa, Second Stage.*—Lena L——, aged twenty-eight, single; United States; neck-tie maker; father living, aged fifty eight; mother living, aged fifty-nine; one brother and one sister living. Never had rheumatism. Present illness dates back about three years. Commenced with pain in side and shoulder, cough, expectoration; she has lost about twenty pounds since that time; appetite fair. Bowels regular. Presents on percussion, right side posterior, dulness down to lower angle of scapula. Left side posterior, dulness of left supra-scapular space. Auscultation, right side, posterior bronchial breathing to middle of scapula, some crepitation at that point. Right side anteriorly (percussion) very slight dulness at apex. Left side anterior, more dulness at apex. Auscultation (anteriorly), nothing abnormal on right side. Tubular breathing left side down to third and fourth rib. Has had no fever-temperature for some time prior to entering hospital.

January 4, 1891. 12 M.: Injection of 0.002 milligr.; 5 P.M.: Temperature, 106.4° F.; 7 P.M.: Temperature, 105.6° F.; 9 P.M.: Temperature, 105.4° F.; vomited twice.

January 5th. 9 A.M.: Temperature, 101.2° F.; 4 P.M.: Temperature, 101.8° F.; injection of 0.002 milligr.; 9.30 P.M.: Temperature, 104.4° F.; slight chill; 11.45 P.M.: Temperature, 106.2° F.

January 6th. 2 A.M.: Temperature, 105.2° F.; 8 A.M.: Temperature, 102.4° F.

CASE XIV. *Phthisis Tuberculosa, Second Stage.*—Harry W— —, aged twenty-one; single; clerk; born in America; father, mother, one brother and two sisters living. Received a scalp-wound eighteen months ago, since which time he dates his trouble. Has had a cough since March 18, 1890, has lost thirty pounds in eighteen months. Now complains of cough, expectoration, and night-sweats. Extremely emaciated; appetite not good; bowels irregular. Temperature 102° F.; pulse, 148.

January 3, 1891. 5 P.M.: Temperature, 102° F.; injection of 0.002 milligr; 11 P.M.: Temperature, 101.2° F.

January 4th. 9 A.M.: Temperature, 100° F.

January 5th. 9 A.M.: Temperature, 99° F.; appetite improved, feels much better. 5 P.M.: Temperature, 101° F.; injection of 0.002 milligr.; 9 P.M.: Temperature, 102.4° F.

January 6th. 7 A.M.: Temperature 99° F.

CASE XV. *Phthisis Pulmonalis Tuberculosa, Second Stage.*—George K——, aged thirty-four, sculptor; married; born in Germany; father died aged sixty-five, cause unknown; mother died aged seventy, cause unknown; two brothers living, two dead; one, aged twenty-seven, died of phthisis; one, aged eighteen, was killed. Never had rheumatism. Present illness dates back about eight months, when it commenced with cough and dyspnœa. Has lost eight pounds in six months. Temperature, 99° F.; pulse, 134; appetite very poor; bowels irregular (constipated).

January 5, 1891. 1 P.M.: Temperature, 99° F.; 5 P.M.: Temperature, 100° F.; injection of 0.001 milligr.

January 6th. 1 A.M.: Temperature, 102.8° F.; 7 A.M.: Temperature, 100.2° F. Sputum contains moderate number of bacilli.

CASES AT THE ST. JOSEPH'S ORPHAN ASYLUM.

By EDMUND CHARLES WENDT, M.D.

Services of DRS. EDMUND CHARLES WENDT and F. KAMMERER.

Five new cases have been selected for treatment by lymph at this institution during the past week, making the total number of cases twelve.

In Case VII. the inoculations were discontinued, as there was no reaction after sufficiently large doses had been reached. According to Koch's doctrine, the condition of this little girl should, therefore, be regarded as at present "non-tubercular." This would accord with the fact previously noted, of her recovery from an attack of meningitis, closely simulating the tubercular variety. This child has certainly not been made worse by the inoculations. Her general condition remains entirely unchanged. In the present stage of experience negative evidence may be just as instructive as that of a positive nature.

CASE I., of previous report. *Strong Hereditary Predisposition to Phthisis.*—Slight cough. No expectoration.

January 2, 1891. Seventh inoculation of 0.004 gm. In eleven hours the temperature had risen from normal to 103.4° F. Headache very severe.

January 3d. Temperature remained at about 101° F. all day until 9 P.M., when it became normal.

January 4th. Slight elevation of temperature to 100° F. this afternoon.

January 5th. A few finely crepitant râles are heard for the first time to-day over left upper posterior portion of lung. Eighth inoculation, temperature 99.2° F. at time of injection of 0.0045 gm. Temperature rose to 102° F. in eight hours.

January 6th. Temperature fluctuated between 101.4° and 102.2° F. Considerable malaise.

CASE II., of previous report. *Ozæna Scrophulosa, Lymphadenitis of Neck.*—January 2d. Seventh inoculation at noon, 0.004 gm.; at 9 P.M., temperature 103° F.

January 3d. Temperature normal. Nasal ulcers healing under crust. Eyes clear, the scleral injection has entirely disappeared. Glands on right side of neck appreciably smaller. Right side still quite large.

January 4th. Eighth inoculation of 0.0045 gm., temperature 98.4° F. at time of injection. Reaction to 101.3° F. in seven hours.

January 6th. Ninth inoculation of 0.005 gm. Moderate reaction. The cough which at first was very troublesome is at present subsiding. Lungs negative, except a few bronchial râles.

CASE III., of previous report. *Hip-joint Disease.*—Reinoculations January 2d and 4th up to 0.003 gm. On the first-named date the temperature rose to 104.4° F.; on the second only to 101.4° F., on both occasions about ten hours after injection.

January 6th. The hip-joint became more painful after injection, but the tenderness is now diminishing. There is greater mobility of joint.

CASE IV., of previous report. *Hip-joint Disease.*—A deep-seated enlarged gland in iliac fossa is more tender than before treatment. Joint motions also more painful. No general symptoms. Only one inoculation of 0.002 was given January 3d. Moderate reaction to 100.4° F. Temperature fluctuates between 100° F. and 100.4° F., without having reached the normal level.

CASE V., of previous report. *Tubercular Glands of Neck and Submaxillary Region; Scrofulous Eyes and Nose.*—December 30th. Temperature rose to 102.4° F.

January 2d. Inoculation of 0.0015 gm. Temperature normal. In ten hours rose to 102.6° F.

January 3d. Skin peeling, exactly like in scarlatina.

January 4th. Inoculation of 0.002 gm. Tempera ture did not rise above 100° F.

January 5th. At 9 P.M. temperature 101.0° F., *i.e.*, late reaction.

January 6th. Inoculation of 0.002 gm., *i.e.*, same as

previous dose. No reaction. Much less cough. Harsh breathing at apices, but no râles.

Case VI., of previous report. *Incipient Phthisis.*—January 1st. Fewer crackling râles, expiration harsh and prolonged at both apices. More dulness on right side.

January 2d. Injection of 0.003 gm. Temperature rose to 104.8° F. A rash closely resembling measles appeared all over body, except legs.

January 4th. Rash not yet entirely faded. Temperature did not return to normal before midnight.

January 5th. Injection of 0.0035 gm. at 1 P.M. This was followed by severe symptoms. Intense headache which made her scream out with pain. Constant coughing. Temperature rose to 101.4° F. by 6 P.M.; at 8 P.M. it was 104.4° F.; at 9 P.M., 105.8° F.; at 10.30 P.M., 104.2° F.

January 6th. At 8 A.M., temperature, 101° F. Feeling of prostration, but no collapse. Less cough.

Case VII.—Injections discontinued.

Remarks on New Cases.—The five cases which follow were selected with a view to testing the lymph in a diagnostic way, in children with manifestations of a merely suspicious character, but without positive signs of actual phthisis. So far as diagnosis is concerned, it seems hardly necessary to further multiply cases of readily demonstrable phthisis in which the lymph shows its effects by producing a reaction.

Cases of undoubted consumption will be watched with interest rather from the curative point of view. But it will require months or years before final conclusions as to the efficacy of the lymph in that direction can be reached. If, however, we accept the doctrine that reaction after inoculation means the presence of tubercle, then diagnostic tests can be made in a comparatively brief space of time. Cases responding could remain under treatment until the absence of further reaction would point to the disappearance of tubercular tissue and the establishment of a cure, at least of a temporary nature.

Cases not responding will presumably not be injured by a few injections of Koch's lymph, particularly when the initial doses are kept as low as one-fourth of a milligram, which is the rule I have at present adopted in treating children.

Case VIII. *Phthisical Thorax; Enlarged Cervical Glands; "Suspicious" Breathing at Apices.*- Girl, aged twelve. Family history good. Is thin and delicate; very narrow and flat chest. The breathing at apices is harsh, but there are no râles of any kind. No cough. Chains of enlarged glands of neck, running down to supra-clavicular region.

January 5th. Injection of 0.00025 gm. In six hours temperature rose to 101° F.

January 6th. A.M., temperature, 99.8° F.; 4 P.M., 102° F.

Case IX. *Scrofulous Ulcerations; Fetid Otorrhœa; Cervical Lymphadenitis.*—Girl, aged eight Lungs negative, no cough. Corneal opacities and various scars indicate former morbid processes. At present only slight ulceration of lip and nose. Chains of enlarged glands on either side of neck.

January 5th. Injection of 0.00025 gm. Temperature rose from 98.4° F. to 99.4° F.

January 6th. Injection of 0.0005 gm.

Case X. *Winter Cough, Suspicious Breathing at Right Apex.*—Girl aged eleven. Has coughed every winter for a number of years. Right supra-clavicular space retracted, expiration harsh and prolonged over this region. No râles. Small eater. Slight glandular chains at neck.

January 5th. Injection of 0.00025 gm. Cough increased; pain in chest. In six hours temperature rose to 101° F.

January 6th. Temperature at 11 A.M., 100° F.; at 4 P.M., 100.6° F.

Case XI. *Suspicious Apices; Hereditary Predisposition to Phthisis.*—Girl, aged fifteen. Parents both died of consumption. One sister "delicate." Has coughed for eight years. Small eater. Paralytic thorax. Slight retraction at apices. Supra-clavicular spaces sunken in during inspiration. Very few râles, apparently bronchitic. Pain over chest.

January 5th. Injection of 0.00025 gm. Temperature did not rise above 99.4° F.

January 6th. Temperature remained almost stationary at 100° F. all day.

Case XII. *Aggravated Pigeon-breast; Ulcerative Processes of Lips and Eyes; Large Cervical Glands.*—Boy, aged ten. Thorax deformed in pronounced pigeon-breast way. Thin, pale, delicate-looking. Lungs negative. No cough.

January 5th. Injection of 0.00025 gm. Temperature rose to 100° F. in four hours.

CASES AT ST. LUKE'S HOSPITAL.

Service of Dr. Francis P. Kinnicutt.

The following case is reported in detail as presenting points of interest.

Case VIII. *Tubercular Infiltration of Apex of Left Lung.*—Male, aged twenty-six. Admitted to hospital November 20th. History of impaired digestion and of cough of no longer duration than four weeks.

Physical Examination.—Slightly impaired resonance in first left interspace, without appreciable auscultatory signs of disease. A regular afternoon rise of temperature, varying between 101° and 103⅘° F., present. Numerous tubercle bacilli in sputa. Patient's weight, 96½ pounds. The ordinary treatment employed in the hospital in phthisical cases was ordered.

Physical Examination Immediately Previous to First Inoculation.—Distinctly impaired percussion resonance over first left interspace and in supraspinal fossa, with moist crepitation appreciable in forced inspiration and after cough. Amount of sputa in twenty-four hours, two ounces. Patient's weight 96½ pounds, the same as three weeks previously.

First inoculation, December 13th, 3 P.M., 0.001 gm. The temperature did not rise higher than had occasionally been noted previously; but at the usual time for reaction the patient complained of pain in chest and there was increased cough and wasting. The sputa increased in the subsequent twenty-four hours to four ounces.

Reinoculations were made on the 15th, 19th, 24th, 26th, 29th, January 1st, 3d, and 5th, gradually increased in strength to 0.003 gm. The increase in the amount of sputa following the first inoculations, with its subsequent gradual diminution was as follows: Amount of sputa in twenty-four hours ending 3 P.M. on the 14th, four ounces; 15th, two and one-half ounces; 16th, four ounces; 17th, two and one-quarter ounces; 18th, one and three-quarter ounce; 19th, one ounce; 20th, one ounce; 21st, nine drachms, until on January 4th it was reduced to four drachms.

The effect of the inoculations given in the afternoon, between three and four o'clock, was at first apparently to produce a morning rise of temperature, equal in degree to the usual afternoon fever. With the continuance of the inoculations, the range of temperature gradually declined. Since December 31st, the highest temperature recorded, taken each hour from 7 A.M. until 10 P.M., has not exceeded 100⅕° F. (in mouth), except immediately following inoculation.

In the reaction subsequent to the afternoon inoculation of January 5th the temperature reached 101⅘° F., on the following morning falling to 99⅘° F., in the afternoon.

The patient's weight on December 22d, nine days after the first inoculation, was 99 pounds; on December 30th, 101 pounds. His general condition has improved proportionately.

Physical Examination on January 4th.—No appreciable crepitation either on forced inspiration or after cough over affected area. The percussion-note over the supra-

spinous fossæ is apparently of the same quality. It is slightly impaired in the first left interspace.

The examination of the sputa has been kindly made by Dr. Prudden, throughout the period of inoculations. The number of bacilli in the total daily amount of sputa has been computed. The diurnal variation has been so great and irregular as to preclude any conclusions at present.

Case IX. *Epithelioma of Hand.*—Successive inoculations of 0.001 gm., 0.002 gm., 0.004 gm., and 0.008 gm. have been unaccompanied by any reaction, either local or general.

In Case VI. of the last report, "no improvement in the cutaneous tuberculosis," should read "marked improvement." It consists in the gradual diminution in the induration and the separation of the compact hard mass into separate nodules, the intervening tissue being of a healthy appearance. In this case the local reactions have consisted in no more than a reddening and sensitiveness of the diseased patch, with the development of a moderate hyperæmic areola. There seems to have been a gradual reabsorption of the diseased tissue.

Koch's Treatment of Tuberculosis in Children.—At a meeting of the Gesellschaft der Charité-Aerzte, on December 4, 1890, Professor Henoch presented a communication on the results of the new treatment of tuberculosis as seen in children. He said he had tried it in eleven cases, the clinical observations extending over a period of fourteen days. The ages of the little patients were from two to eleven years, and the diseases from which they suffered were as follows: Pulmonary tuberculosis, 6 cases; lupus, with vertebral caries, 1; caries of the petrous portion of the temporal bone, with chronic peritonitis, 1; tuberculous meningitis in the last stage, 1; scrofulosis, 1, and spina ventosa, 1. He began in all cases with injections of one-tenth of a milligramme. As no reaction followed this dose it was increased to two-tenths, and afterward to three-tenths, this being the smallest dose which produced any reaction. The intensity of the reaction was, however, very variable, and did not appear to bear any definite relation to the age of the patient. Thus some of the younger children (aged from two to three) did not seem to be in any way affected by an injection of three-tenths of a milligramme. This dose made the temperature of a boy, aged eight, with consolidation at the apex, rise to 38.4° C. In two children in whom tuberculosis was suspected, four-tenths of a milligramme sent the temperature up to 38.2° C., and caused great restlessness and prostration. A child two and a half years old, with tuberculous meningitis in the last stage, showed moderate reaction after each injection, three-tenths of a milligramme being first given, and the dose being gradually increased. In a child of the same age, with spina ventosa, a dose of three-tenths of a milligramme caused a reaction which lasted three days, the temperature reaching 39° C., and the respiration being quickened to 60 to 70 per minute, with great prostration and much swelling and redness of the affected part. A boy, aged seven, with pulmonary phthisis, required a dose of eight-tenths of a milligramme before reaction could be produced. In the child, aged four and a half, with caries of the petrous bone and chronic peritonitis, who had undergone scraping of the bone and paracentesis of the abdomen, two injections of four and five-tenths of a milligramme respectively, given at an interval of one day, caused redness about the wound over the petrous bone, and fresh effusion into the peritoneal cavity. The latter disappeared after a few days. In the case of the child with tuberculous meningitis, four injections (of three, four, five, and seven-tenths of a milligramme respectively) were given. The child died, and on *post-mortem* examination (made by Virchow) the brain and meninges were hyperæmic instead of pale, as they usually are from the pressure of the distended lateral ventricles. This shows, according to Henoch, that Koch's treatment is absolutely contra-indicated in tuberculous meningitis, even in its earliest stages.

THE LATEST FROM BERLIN.

[The following from Dr. Graefe, one of our correspondents from Berlin, who has just arrived on his way to his native city, Sandusky, O., will be read with interest by those who have followed his former instructive and graphic epistles.]

To the Editor of the Medical Record.

New York, January 5, 1891.

Sir: Having in my former letters from Berlin given the results of the experiments with the Koch lymph from the beginning of the public demonstrations, with your permission I will bring a record of my observations to the date on which I left. The fact that the lymph will produce a well-defined local and febrile reaction has been verified by hundreds of experiments, but it has also been shown that there are many exceptions to the rule—that is, quite a percentage of cases which are known to be tubercular do not react and others which are not tubercular have in a few cases reacted. Professor Ewald and Dr. Neuhaus have denied, in a meeting of the Berliner Medicinische Gesellschaft, that the changes which are said to take place in the expectorated bacilli can be found in these cases; and Dr. Sonnenburg has, under the direction of Professor Koch, been making operations on the lungs to get rid of the detritus produced by ulcerating cavities and the application of the lymph. In surgical cases Professors von Bergmann and Hahn and Drs. Westphal and Kohler are on record as saying that macroscopically the joints in coxitis and gonitis do not differ materially upon operation from those where no lymph has been used.

The results of examination with the microscope have as yet not been extensive enough to warrant any final conclusions, but those which have been made show the tendency to destruction claimed and the presence of bacilli. Professor von Bergmann has operated upon his cases of joint disease, after a course of Koch injections, when the patients ceased to react upon the repeated application of large doses. In one case of hip disease, in a boy about eleven years of age, there was considerable destruction of the joint, and it was reported that the patient died after an uncomplicated resection. In other cases it was found necessary to remove the diseased tissue with the curette, besides opening up the tubercular cavities in the bones. The Professor said that if the lymph could produce an immunity in the diseased tissue from fresh attacks of the bacilli its value would be great in these cases, but as Koch himself only claims a destruction of tissue, with the setting free of the bacilli contained therein, and points out the danger of reinfection if the bacilli are not removed by operation, the efficacy of the treatment in joint troubles must be considered questionable for the present.

Through the courtesy of Professor Hahn I was permitted to carefully observe all the cases under treatment at the Berliner Allgemeines Krankenhaus.

Profiting by the experiences of others, the Professor operated upon his cases after a number of applications of the lymph and continued the treatment after operation. It seemed in these cases that firm healthy granulations appeared very quickly to take the place of the tubercular tissue removed by the curette, and the fistulæ soon closed, but any local stimulation which would produce a flow of blood to the parts might do the same. In the best case of lupus in this hospital, very superficial nodules on the face and neck, an erythema was produced by the lymph over the whole body, ending in a desquamation which removed all the crusts and skin except at the edge of lupus ulcer. In a case where the Professor had made a resection of the knee four months before and where bacilli were found in the sputum, there was no febrile reaction, but upon opening the joint it was found that it was filled with soft tubercular granulations, but there was no bony union. The case looked like a good one for amputation.

Professor Hahn is recognized as an authority in surgical diseases of the kidney, and in a case where he diagnosed and evacuated three abscesses, though no bacilli could be found in the urine, the patient reacted with a temperature

of 40° F. There have been a number of deaths, one occurring in the hospital at Innsbruck being caused by the extension of the inflammation from about the tubercular tissue in the lungs, producing a double pneumonia. Two deaths occurred at Friederichshain, the patients being children, and a number of cases of collapse with subnormal temperatures have occurred, though the doses at this hospital were always very small. A case at the Koenigiliche Clinic shows that the remedy is a two-edged sword in other ways, for an Englishman who had a very small lupus ulcer on the end of his nose was confined to his bed by a fresh attack of hip disease in a joint that had been affected twenty years before and had not troubled him since.

Czerny reports paralysis produced in a case of caries of the vertebræ and Hahn has a case where paralysis began to disappear after the third injection. There is no doubt but that the lymph will produce an inflammatory action in and about tubercular tissue, but it is not scientific or reasonable to expect more than this, especially as Koch himself assures us that it will not kill the bacilli which he considers the cause of the disease. Its diagnostic value must be great, for its aid in differential diagnosis will be valuable, and in every case it is easier to make an injection than to make a microscopical examination for bacilli.

The therapeutical value, according to experiences up to date, would seem to be limited to superficial tubercular ulcerations, or those which can be made so by the surgeon, except in those early cases which are seldom diagnosed, where the tubercular deposits are so small that they can be destroyed, or stimulated to absorption by the local congestion produced by the lymph, without endangering the system by this absorption.

As to anything more than this, the authorities abroad seem to be agreed that it will be a matter of time to determine if the results attained will be permanent and if the lymph will ever take a place as a therapeutical agent in the future except as mentioned above.

Obituary.

COERT DUBOIS, M.D.,

NEW YORK.

Dr. Dubois died on the night of January 1, 1891. I feel sure that I shall meet the wishes of the many friends of the late Dr. Coert DuBois by giving them an account of his last illness and death. He had reached his forty-third year, was a man of florid complexion and full habit, and of rather sedentary tastes, taking little active exercise and passing much of his time in reading.

About two years ago he had his first attack of gout, and since that time has had a succession of attacks, which were very rapidly leaving their deforming effects upon his feet. About a fortnight before his death cardiac symptoms developed, consisting in shortness of breath, substernal pain, and a sense of slight anxiety about the chest. Although careful auscultation revealed no morbid valvular sounds whatever, it was evident that cardiac trouble of muscular character existed. On the day before his death I proposed a short walk to him, to which he agreed with the half-jesting apology, "You must excuse me if I should drop dead on the way." This was said with a laugh, but before the walk was ended I became convinced that there were good grounds for his fears. His respiration was so much impeded that I persuaded him to return home before he had gone far.

On New Year's night Dr. DuBois went to bed at ten o'clock, feeling quite comfortable to all appearances: in just twelve hours from that time he was found sleeping quietly the sleep of death. He had evidently passed away peacefully, without struggle and without pain.

Born of an ancient and well-known family in Hudson, N. Y., Dr. DuBois graduated in medicine in the College of Physicians and Surgeons of this city in 1872, since which time he has practised his profession here. Of a peculiarly modest and shrinking disposition, he lacked those harder elements of character which fit one for success in the sharp struggle for existence in a metropolis, and he came little into general notice and attracted little attention outside of the circle of close and intimate friends who knew his sterling virtues, appreciated his noble nature, and loved him for his distinguished sincerity and loyalty. His was a character which by its tenderness, its simplicity, and its kindliness shone under the genial light of appreciative friendship, not under that which must be borne upon the journey which leads through contention and rivalry to brilliant success. A character, likewise, which excited the deepest affection, and his loss has caused a profound sorrow in the hearts of those who knew and loved him well. T. Gaillard Thomas, M.D.

HUGH OWEN THOMAS,

LIVERPOOL, ENG.

Hugh Owen Thomas, M.R.C.S. Eng., Member of the Royal College of Medicine and Surgery of Cadiz, Consulting Surgeon of the Iron Ship Builders and Boiler Makers of Great Britain and Ireland, Corresponding Member of the American Orthopedic Association, is dead. He was the author of "Diseases of the Hip, Knee, and Ankle Joints," "Intestinal Diseases and Obstruction," "Principles of the Treatment of Diseased Joints," "The Treatment of Fractures, Dislocations, Diseases, and Deformities of the Bones of the Trunk and of the Upper Extremities," "The Treatment of Fractures of the Lower Jaw," "The Principles of the Treatment of Fractures and Dislocations," "Fractures of the Neck of the Femur," "Nerve Inhibition and its Relation to the Practice of Medicine," "An Argument with the Censor of St. Luke's Hospital, New York." and numerous short papers for the medical journals. Recently, he has been at work putting into condensed form his teaching in bone and joint troubles, having especially in view the illustration of the mechanical means employed by him in the treatment of fractures of the bones and diseases of the joints. He was the inventor of the splints which bear his name for the hip, knee, and ankle, of a collar for cervical Pott's disease, of splints for bow-legs and knock-knee, of a shoe for flat-foot, and another for inflammation of the toe-joints, of an aspirator, of a surgical chair for reducing dislocations of the shoulder- and elbow-joints, of a "gauge halter" for the treatment of diseases and injuries of the elbow-joint, of a brace for drop wrist, of a "talipes lever," of an instrument for reducing otherwise irreducible dislocation of the first phalanx of the thumb, of an intestinal trocar and cannula, of a clamp for fractures of the lower jaw, of a splint for fractures of the shaft of the femur, of a support for stumps after amputation, of a splint for fractures of the patella which relieved the patient from confinement to bed—and of minor instruments and tools almost without number. He introduced a new method of testing for hip disease, of treating fractures of the neck of the femur, of treating delayed union in fractured bones wherever located, namely, by "hammering and damming," he devised and practised novel methods of recent and ancient dislocations at the shoulder, of the acromial end of the clavicle, at the elbow, and at the hip joints. His writings are simply narrations of his new devices and methods and the results thereby obtained, with no little pointed criticism of the methods and views of those who were opposed to him in their surgical work. For thirty-four years he worked without a vacation of even one day; only during the past summer was he prevailed upon by his family to go away for a rest of two days. He knew no social life, but only his patients, his books, and his work room. He was a bitter and unforgiving enemy; a devoted and generous friend. To his friend he gave without stint of money, anything. Of late years few American surgeons have passed through Liverpool without spending at least one day with him, and the little shrunken, energetic form, the spectacles, the cap, and the cigarette will be missed by as many here as there.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, December 8, 1890.

ROBERT ABBE, M.D., CHAIRMAN.

Report of a Case of Pistol shot Wound of the Brain.—DR. JOHN A. WYETH reported the case, that of a boy, eight years of age, who was admitted to Mount Sinai Hospital, October 31st. Half an hour before admission he had been accidentally shot by a pistol, size 22, in the hands of his brother, who stood at a distance of about three feet directly in front of him, the ball striking the forehead. It caused hemorrhage and severe pain, but no other symptoms. On admission the patient was rational, calm, the pulse good. About one inch above the middle of the right eyebrow was a wound with depressed edges. He had walked in without assistance; vision was good in both eyes. He was taken immediately by the house surgeon to the operating-room, where, under antiseptic precautions, and under chloroform anæsthesia, he made an incision through the skin, lifted the periosteum, and removed several loose pieces of bone from the wound. A large spicula of the inner table was found and removed. Fluhrer's probe was introduced into the wound in the brain a quarter of an inch. At this point the patient began to vomit; the operator placed his finger over the wound, and on raising it there was a sudden gush of dark, clotted blood and particles of white brain substance. The wound was then dressed. The patient became very pale toward the conclusion of the operation, the pulse became weak, and stimulants were given hypodermically. The next day the patient vomited a little, the temperature rose slightly; the following day the temperature was normal. The third day there was severe pain over the region of the occipital bone, a little to the left of the median line. An ice-bag was applied. The fourth day, November 3d, the temperature rose to 104.2° F., pulse, 130, respirations, 30; patient crying; during the night he was delirious. November 4th the temperature had fallen to 103° F. The wound was dressed under chloroform, found aseptic. By November 7th the temperature was about normal, the patient comfortable except for some pain in the region of the right ear. On the 8th the wound was again dressed, about half an ounce of blood-clot and broken-down brain substance welled out, also a little blood and serous fluid, but no pus was contained in the discharge. The patient went on to do well, and on the 15th the wound was dressed again, and found clean and healing over. At the last observation the wound had healed, the patient was cheerful, felt no inconvenience from the loss of brain tissue or presence of the bullet in the brain. He would be kept quiet another month to give more time for the ball to become encapsulated.

Dr. Wyeth said he would have been strongly tempted to probe more deeply for the ball had he seen the patient when he first entered, but since the house surgeon had operated and cleaned the wound, he did not afterward feel justified in doing this. Thus far it seemed that the proper thing had been done in letting the bullet alone. He believed the boy would have no further inconvenience from the foreign body. He would like to have had Dr. Girdner's electrical instrument for locating the bullet, which he regarded as excellent for that purpose, and he regretted that the Bell Telephone Company would not allow its manufacture for surgical purposes.

Statistics Showing Results after Removal and Non-removal of Bullets from the Brain.—DR. J. D. BRYANT said his own experience with cases of the kind narrated by Dr. Wyeth was limited to two. Some years ago he had became interested in the statistics bearing on the question of foreign bodies within the cranium, particularly when of the nature of bullets. He investigated every case reported by Mr. Wharton in 1879, he believed over 369, and found that in 216 the injury had been caused entirely by bullets, parts of bullets, or buckshot. In 66 the foreign bodies were removed, in 170 they remained. The result was that the recoveries were seventeen per cent. greater among cases in which the foreign body was removed than among those in which it was permitted to remain. Subsequently one of his college assistants made investigations with regard to the lobe of the brain injured. He was able to collect 140 cases; the exact number in which the foreign body was removed or allowed to remain could not be recalled, but the percentage of recoveries was 13.5 greater where the ball was removed. In quite a number of cases the frontal lobe alone was injured, and among these cases the percentage of recoveries was greater when the foreign body was not removed than when removed. Where the parietal lobe was involved the percentage of recoveries was greater when the foreign body was removed; the same was true with regard to the spheno-temporal lobe. When the cerebellum was injured nearly all cases died, irrespective of treatment.

The two important questions were, Was it advisable to do anything? and if so, How should it be accomplished? He was convinced that an attempt to remove the foreign body was perfectly justifiable, but, of course, within certain limits, each case resting largely upon its own basis.

The first case seen by him was one in which the bullet had entered just above the zigoma on the left side. He introduced a probe, which measured perhaps twice the width of the cranial cavity. It passed through and struck the opposite side of the cranium. He then passed one string over the skull in the same plane as the projecting portion of the probe, another around the forehead, also in the plane of the projecting portion of the probe, the angle where these two strings crossed of necessity passing over the inner end of the probe. There he trephined, and located the end of the probe and also the indentation of the bullet on the bone.

The other case occurred last summer, Dr. Girdner seeing the patient with him and using the telephonic probe. With this instrument there was no difficulty in locating the bullet, but there was difficulty after removing it in catching the bullet with forceps. In fact, he had to abandon attempts to remove the bullet, since it was located near the base and if moved might have led to very serious results. He then suggested to Dr. Girdner the desirability of having a probe made in connection with a bullet forceps. He hoped the idea would be carried out.

A Telephonic Probe Improvised from the Telephone Receiver.—DR. JOHN GIRDNER said the Bell Telephone Company had denied permission to manufacture the telephonic probe, and consequently, owing to circumstances over which he had no control, he, Dr. Girdner, had had a monopoly of the instrument. During the past three years he had tested it in eight cases of gunshot wound of the brain. It acted perfectly; whenever the bullet was touched it gave the signal at once. From his observation in these cases he reached the conclusion that if the bullet lay above the plane of the lateral sinus, although the chances of recovery were not good, yet there was ground for hope; if below this plane, the patient would die. He had seen the brain after autopsy in three of the cases, one having died seven weeks after the injury, one five, and the other three weeks, and in all the bullet had lodged in brain tissue and had travelled. He believed, then, that the ball would always travel when situated in brain tissue. He doubted if it would ever become encysted if located in brain tissue alone and not in the neighborhood of membranes containing fibrous structure.

Speaking, again, of the working of the instrument, he said some had objected to its use, because disliking to pierce the brain with a sharp probe. This objection could be overcome by using a fine probe with a blunt end. One could find the bullet with the telephonic probe, but the difficulty was to extract it. He had told a surgi-

cal instrument-maker of Dr. Bryant's suggestion, and it was thought it could be carried out.

On the statement of Mr. Bell, he had supposed the receiver of the ordinary telephone would not answer in connection with the telephonic probe, but, happily, during some experiments he had found this was not true. With this receiver placed to the ear, and one copper wire connected with the probe in contact with the bullet, and another connected with a metal in the hand of the patient, the metal being of the same nature as that of the probe, the telephonic report would be as perfect as could be desired.

Angio-Lipoma of the Face.—Dr. Willy Meyer presented a boy, aged twelve, on whom he had operated for angio-lipoma, covering almost the entire left side of the face, extending somewhat up on the temporal region and on the ear. There was a small growth at birth which slowly extended until the past year, when it developed rapidly and attained to the size mentioned. It was treated by dividing it into smaller areas at a number of sittings, by the Paquelin cautery, which finally deprived the growth of its blood supply. When the knife was resorted to hemorrhage was further controlled by Esmarch's bandage around the head, and by pressure upon the arteries exerted through the mouth. The growth had not been attacked just below the ear lest the facial nerve should be disturbed. This would have to receive further attention. The result had been quite satisfactory.

Dr. Wyeth remarked that tumors of the lymph-ducts were rare yet it was desirable to treat them in the best way when they did come under observation. He had treated a lymphangiectasis by quilting through the tumor with silk previously soaked in tincture or perchloride of iron, and had also operated upon two cases of simple angiomata in the same way. The method proved exceedingly satisfactory. The tumors were solidified by the iron salt, and could afterward be dissected out without leaving any disfiguring scar. The lymph tumor required no dissection afterward.

The Chairman thought the method mentioned by Dr. Wyeth would be the safest in that part of the tumor near the facial nerve in Dr. Meyer's case. He had himself applied the method in two cases about the shoulder blade, inserting perhaps thirty or forty sutures, which had dried after having been dipped in tincture of iron. They were left in two weeks, then pulled out. No sepsis occurred. Cicatricial lines were formed which cut off the vascular supply.

Three Cases of Pylorectomy for Cancer of the Stomach.—Dr. W. T. Bull read the paper (see p. 39).

Gastro-Enterostomy for Pyloric Stenosis.—Dr. R. F. Weir read the paper (see p. 37).

Dr. Wyeth, being asked to open the discussion, said he had not performed either gastro-enterostomy or pylorectomy, but judging from the improved method of doing the latter operation, as described by Dr. Bull, he thought surgeons would come to give it the preference.

Raw-hide Rings.—Speaking of rings, mention had not been made of raw hide used for this purpose, as proposed by Robinson. He thought this material would be found very valuable, with it the rings could be made of any desired size.

Leans to Pylorectomy.—Dr. Willy Meyer thought that, although he had not performed pylorectomy, there could be no doubt it had a field of usefulness. In selected cases it must save or prolong life, more so than gastro-enterostomy could do. He preferred it to the latter operation. He thought the patient should be given fluid food as early as the third day after the operation.

Operate Early.—Dr. B. F. Curtis thought the future of pylorectomy for cancer would depend largely upon the family physician. In other words, upon how early the diagnosis was made and the patient sent to the surgeon for the operation. So far pylorectomy had been performed almost solely upon desperate cases. The hydrochloric acid test was becoming more and more reliable in diagnosis. Moreover, in doubtful cases an exploratory operation was now quite justifiable, for, although cancer might not be found, yet one of several other conditions might be present which had come to justify an operation. Dr. Bull's third case gave encouragement, even in cases of large tumors which were not adherent, and which were unaccompanied by constitutional infection. He doubted whether the use of rings had tended to shorten the operation of gastro-enterostomy very much. They were not so easily applied as in operations on the intestine alone. The reason why the rings had not shortened the operation was that men were afraid to trust to them without sutures, and the introduction of these prolonged the operation. Gastro-enterostomy had been performed in Berlin in half an hour without rings, by use of interrupted sutures. At the same time, Dr. Weir's statistics on the mortality rate spoke very well for gastro-enterostomy with the rings.

Make Two Operations.—Dr. Curtis thought gastro-enterostomy might well be done first, and at a subsequent operation remove the tumor, for it was in doing this that most blood was lost and the single operation much prolonged.

Dr. Abbe presented some catgut rings two and three inches in diameter. The first line of sutures should be in place before the stomach or intestine was opened. He thought the suggestion to make of gastro-enterostomy and removal of the tumor two operations a valuable one. Regarding the relative merits of pylorectomy and gastro-enterostomy, he thought that if the former required two hours or two hours and a half when performed by men of Billroth's experience, and gave a mortality of fifty per cent., that it could not come into use by surgeons generally. Gastro-enterostomy had a simpler technique and would be possible with any surgeon.

Dr. Kammerer had seen pylorectomy done, and agreed with his colleague, Dr. Meyer, that suturing the divided end of the duodenum to the stomach was to be preferred to gastro-enterostomy as described in Dr. Weir's paper. He thought Senn's plate might be used in pylorectomy after first suturing the upper part of the incision in the stomach. As regards intestinal anastomosis by use of the rings, he had operated in three cases, two for gastro-enterostomy, in all with a fatal result. In the first case the portion of the ring in the stomach was found at autopsy digested, while the portion in the duodenum was intact. This giving way of the ring had caused death. The second patient died of exhaustion on the second day; the ring was found intact, anastomosis complete. The third case was different, being an ileo colostomy for cancer of the cæcum. Post-mortem on the third day: the ring in the ileum was entirely gone, the one in the colon was distorted, thus they had given way and the patient died of peritonitis. He did not think it safe to use the rings without many sutures, else they would snarl. He had prepared them strictly according to Abbe's method. He thought Senn's plates might do better in gastro-enterostomy than the rings.

Dr. Bull said he had taken a somewhat conservative view; he did not advocate pylorectomy in every case of cancer. As had been suggested by Dr. Curtis, cases should be sought early. Physicians who had patients with dyspepsia should examine for cancer or a tumor. The question of attempting the operation in two stages, also suggested by Dr. Curtis, had occurred to him, although he had failed to mention it in his paper. He thought it would be a desirable method, especially in somewhat advanced cases. The catgut rings could be made so they would not twist, and he thought they fulfilled the indications better than any other yet brought forward.

Dr. Weir said he would recede from his position only after the conditions bearing on pylorectomy mentioned in the discussion had been put in use and found an advantage. The weightiest argument which they could bring forward would be to reduce the mortality. Regard-

ing the rings, in placing them especial attention should be given the outer suture on which the traction came. These applied properly, the rings would retain their place until anastomosis had made things secure.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, September 24, 1890.

H. P. Loomis, M.D., Vice-President, in the Chair.

Tuberculosis of the Pericardium.—Dr. H. M. Biggs presented some specimens removed from the body of an Italian who died in Bellevue Hospital. He was admitted to the hospital thirty-six hours before death, having at that time a weak and rapid pulse and a distended abdomen, but no history of his illness could be obtained, and he died without any diagnosis having been made. At the autopsy there was found to be tuberculosis of the peritoneum of the usual type. The lungs were adherent on both sides, the adhesions being very extensive, but no tubercular lesions were found in them. The two layers of the pericardium were adherent, and between these two layers were two large and a number of small cheesy masses. The large mass was about 6 ctm. in diameter and 2 ctm. in thickness, and was surrounded by very dense connective tissue. These specimens illustrated an unusual type of tuberculosis. Apparently it was a case of primary tuberculosis of the pericardium in which recovery had seemingly taken place, the tubercles having become surrounded by connective tissue. Dr. Biggs believed that there had also been a pleuritis as well as a pericarditis, and this had given rise to the adhesions. He thought that it was not infrequent that in tuberculosis of the pleura, the tubercles being small, later degenerated and became absorbed, leaving no trace of their presence. Of course it was not possible to prove this view. The bronchial glands in this case were apparently not enlarged.

Biliary Calculus.—Dr. R. G. Freeman presented a biliary calculus, which had been removed from the body of a woman forty-five years of age, who was poorly nourished, and somewhat jaundiced. The specimen nearly filled the gall-bladder, and fairly represented its shape. It was surrounded by a little grayish-looking fluid. This stone, which was five and one-half centimetres long, and two and one-half centimetres in its greatest width, weighed nineteen grammes. On section, it was found to consist chiefly of inspissated bile, and contained two cholesterine stones; one at the neck, one and one-half centimetre, and the other at the fundus, one centimetre in diameter. The cystic duct was impervious.

Dr. Freeman also presented a gall bladder which had been obtained by Dr. Hodenpyl from the body of a man sixty-nine years of age, who died from an injury received while in apparent good health. The autopsy showed endocarditis and interstitial myocarditis, the pneumonia of heart disease, cirrhosis of the liver, interstitial pancreatitis, and chronic diffuse nephritis. The gall-bladder was hard, and its walls greatly thickened. It contained a number of small biliary calculi. The cystic duct was pervious.

Stated Meeting, October 22, 1890.

J. West Roosevelt, M.D., President, in the Chair.

A Case of Pseudo-Leukæmia.—Dr. William P. Northrup presented a report of such a case illustrated by microscope specimens showing a lymph-node and the small bodies found in the spleen and liver. The history covered a period of thirteen months previous to the death of the child, and began with the statement of the nurse, that a lump appeared on the side of the neck about two months before she returned the child to the New York Foundling Asylum for inspection. The patient was aged four years and two months. Examination showed a large mass occupying the right side of the neck, consisting of small, discrete tumors like enlarged glands, which were fairly movable. The overlying skin was normal, and the patient's general health good. During the last year of life the child contracted scarlatina, from which he recovered without nephritis. The tumor steadily increased in size, and six months before death Dr. Poore, the consulting surgeon, performed an exploratory operation. He removed a number of enlarged lymph-nodes which were reserved for examination, but it was found impossible to remove all. The child made a good recovery from the operation, but about this time the patient passed into a decline, which was marked by pronounced anæmia, anorexia, enlargement of numerous other lymph-nodes throughout the body, enlargement of the spleen, and rapid and feeble heart-action, irregular and sudden marked increase in the temperature, accompanied by rapid respirations, sixty or more per minute, and a pulse of two hundred. Physical examination of the lungs remained negative throughout the course of the disease. In the intervals between the exacerbations referred to the child was fairly comfortable, except for a diarrhœa, which grew gradually more severe, and finally became uncontrollable. For two weeks the respiration was croupy, noisy inspiration and expiration, and this was thought to be the result of pressure of the tumor. Death occurred thirteen months after the first symptoms were observed.

At the autopsy the body was found to be emaciated, and a diffused swelling on the right side of the neck extended from the ear to the clavicle, bounded in front by the median line, and behind by the shoulder. An incision into this region showed a collection of glands reaching from the ear to the axilla, and closely resembling a large bunch of grapes. When removed, the mass brought with it the middle third of the clavicle. The lymph-nodes varied but little in size, and each was surrounded by a separate capsule of thickened fibrous tissue. The nodes, on section, were white and glistening, firm, and not cheesy, and were totally unlike tuberculous nodules. Large, isolated lymph-nodes were also found in the left axilla, and in both inguinal regions. The lungs were quite œdematous, and contained fine miliary bodies like tubercle, and scattered areas of consolidation. The bronchial lymph-nodes were neither cheesy nor chalky, and were not tubercular. The liver contained dull-white, stellate, and irregularly shaped masses, varying in size from two to six millimetres, and the lymph-nodes at the portal entrance were large and white, but not cheesy. The spleen was much thicker than normal, irregularly nodulated on its surface, which showed indistinctly, before section, small white bodies. On section, these bodies, which were plainly visible against the dark background of splenic tissue, appeared like irregular masses of fat scattered thickly through the organ. The kidneys were pale, and the markings normal, but no white bodies were present. The stomach and intestines showed only a moderate catarrh. The cervical, axillary, mediastinal, retro-peritoneal, and inguinal lymph-nodes were only moderately enlarged, being about the size of the domestic hickory nut. There was marked anæmia, with moderate œdema of the mediastinum and peritoneum, but none of the legs. The microscopical examination of these lymph-nodes, and of the areas already described in the liver and spleen, showed small round cells in abundance, spindle cells, giant cells, polygonal cells, and new blood-vessels. The blood had been examined, but not properly. So far as the examination went, it showed no very marked change in the relation of the white to the red blood-corpuscles. The structure seen under the microscope seemed to him very much like that of a sarcoma.

Dr. T. Mitchell Prudden spoke of the confused nomenclature of this disease. The term lymphadenitis was particularly objectionable, for the parts principally involved were not the glands, and these tumors in their growth did not produce a glandular structure. He

thought the term adenie was the least objectionable of the many that had been proposed.

Pachymeningitis Interna Hæmorrhagica.— Dr. E. D. Fischer presented a report of such a case, and exhibited the brain. The patient was a man seventy-two years of age, an inmate of the almshouse, and apparantly in good health before the attack. Suddenly one evening, about nine o'clock, he was noticed to be breathing noisily, and on summoning the physician the patient was found to be unconscious, with stertorous respiration, full pulse, unequal pupils, but with no signs of paralysis. There were no other symptoms up to the time of his death, on the following morning. The history seemed to bear out the diagnosis made at that time, of apoplexy, or intracerebral hemorrhage. Dr. Fisher said the autopsy showed all the organs to be healthy with the exception of the brain. On the right side, between the dura mater and pia, there was an effusion of blood, one portion of which was enclosed in a distinct membrane. This looked as though there had been a previous inflammation of the dura, giving rise to an increase of tissue. The effused blood did not seem to come from any other portion of the brain except the new tissue which had formed in the course of a pachymeningitis. The brain showed no pressure on the convolutions at the site of the hemorrhage. The arteries exhibited marked atheromatous degeneration. Although these cases are spoken of in the books as rare, they occurred with comparative frequency in the almshouse, and almost always had a previous history of alcoholism, and frequently also of syphilis. He desired to know whether an examination of the specimen would throw any light upon the character of the hemorrhage, and also how frequently these cases are met with at necropsies. It had been considered that this condition was not uncommon in general paresis of the insane; but he had witnessed many necropsies on such cases, and had not found it very frequently present.

Dr. H. M. Biggs said that his pathological observations included many of those who died in "the cells" of Bellevue Hospital, and among these this condition was by no means infrequent. Since his return to the city this fall he had seen at least three cases of pachymeningitis with cortical hemorrhage and death. The subject was of great practical importance, in view of the advances made in cerebral surgery. It seemed as though there should be some way of diagnosticating cortical from intracerebral hemorrhage. He had frequently seen cases of cortical hemorrhage where an operation would apparently have given relief. It was not only in these cases of pachymeningitis with cortical hemorrhage, but in cases of traumatism with or without fracture of the brain, where there was little or no laceration—and there were a great many of these—that the chances of recovery would be excellent if a correct diagnosis could be made. So far as he had been able to learn the clinical history of these cases, paralysis was not usually present, but when it did exist it was not on the same side as the lesion, and was apparently due to increase of intracranial pressure. On the side opposite to the lesion there was much more likely to be rigidity than paralysis. Coma, when present, was usually profound, and there was generally some irregularity of the pupils.

The President asked Dr. Biggs if in his experience pachymeningitis, with a thin membrane, was not commonly found in cases where there was no particular evidence of hemorrhage—in other words, where the clinical picture was that of apoplexy?

Dr. Biggs replied that he had frequently seen cases where the membrane was of considerable thickness—about one-sixteenth of an inch—in which death occurred without evident determining cause, and where there were no recent hemorrhages or signs of pressure.

The President said that he had observed cases in which there was general disease of the larger cerebral vessels with symptoms of apoplexy, but without hemorrhage, in which sudden death had occurred, sometimes with a convulsive attack on the side which was subsequently paralyzed. He would like to know about the frequency with which such cases occur.

Dr. Fisher said that in Gowers' recent work they are spoken of as rare.

Dr. Holt had met with two cases in children, in about four hundred and fifty autopsies.

Dr. Northrup had reported to the Society five or six cases occurring in children, and in his experience it was quite frequent among asylum children. In answer to a question from Dr. Biggs, as to whether he had found in children the same kind of hemorrhages as in adults, he replied that small hemorrhages were very common, but they occurred in poor, miserable children where there were other causes more likely to produce death. The hemorrhages were usually punctate; and he did not recall having seen a layer thicker than blotting-paper.

Cerebro-spinal Meningitis.—Dr. L. Emmett Holt presented a report of such a case, and Dr. T. Mitchell Prudden presented a report upon the bacteriological examination of the specimens, and the demonstration of the presence of the pneumococcus of meningitis (see p. 43). He also exhibited the cultures and slides showing the pneumococci from the exudate.

Dr. Walter Mendelson said that every observer was impressed with the great disproportion between the nervous symptoms and the extent of the pathological lesions in this disease. He had had an opportunity of witnessing many cases while in the New York Hospital, and he recalled very distinctly what great variations they presented. One case, presenting but few symptoms, would be found on post-mortem examination to exhibit an abundant exudation of pus over the brain and spinal cord; while in another, with marked nervous symptoms, perhaps only a few small patches of exudation here and there would be seen. This forced us to the conclusion that death was not produced by the involvement of the nervous system, so much as from poisoning of the system by a ptomaine, or something of that nature. He asked if in Dr. Holt's case the diagnosis had been made before death.

Dr. Holt replied that he had not seen the case during life, but that it had been observed by a competent house physician, and that meningitis had not even been suspected; and, in fact, there were no nervous symptoms present up to twelve hours before death. He recalled one case which had been repeatedly examined by several others besides himself, and no one of the observers suspected meningitis; yet the autopsy showed that, in addition to the meningitis, there was a well-marked lobar pneumonia, which had caused the child's death. This was in striking contrast with the well-known fact that children with pneumonia often had intense cerebral symptoms without meningitis.

Dr. Biggs reported a case bearing upon the relation of the pneumococcus to meningitis. It was one of double lobar pneumonia and meningitis, which occurred at Bellevue Hospital, and where cultures from the meningeal exudate showed the presence of the Fraenkel's pneumococcus.

Dr. Louis Waldstein inquired particularly concerning the relation of the pulse, respiration, and temperature in Dr. Holt's case, for, as cerebro-spinal meningitis must be looked upon as an infectious disease, due probably to the circulation of some toxic principle in the blood, he wished to know the effect of this poison upon these vital signs.

Regarding the connection of the child's fall with the case, Dr. Fisher believed that it was entirely independent of the subsequent history.

Dr. Prudden, on the other hand, thought it might be a very significant feature, for two factors must be recognized in the production of an acute infectious disease, *i.e.*, the predisposing and the determining causes. The child's fall might have caused a change in the brain which predisposed it to the lodgement and growth of these germs; a charge so slight that it might not have caused any trouble if these germs had not been present.

The President commented upon the great scientific value of a report of a case which had been so well observed, and said that he thought the relation of the bacterium to the disease was the most important element in the case. The connection of these micrococci with two diseases, cerebro-spinal meningitis and pneumonia, was very curious; for the former usually occurred in epidemics, which were frequently complicated by pneumonia, while the latter was constantly present.

OUR LONDON LETTER.

(From our Special Correspondent.)

KOCH'S METHOD—PULMONARY HYDATID CYST—THE BRADSHAW LECTURE AT THE COLLEGE OF SURGEONS—SIR SPENCER WELLS ON ANÆSTHETICS AND DRAINAGE—THE RECONSTITUTION OF THE UNIVERSITY OF LONDON.

London, December 20, 1890.

At the last meeting of the Clinical Society, Dr. Pringle and Mr. Malcolm Morris, showed the patient whom they had taken to Berlin to be treated by Koch's method for lupus of the mouth and face. Considerable improvement had taken place. The ulcerating surface on the skin had cicatrized, and the roof of the mouth was much better.

At the same meeting of the society, Dr. Bristowe described a case of hydatid of the lung in which death took place after an exploratory puncture. The patient was a boy of nine, who had enjoyed good health until a fortnight before admission into hospital. The movement of the chest was imperfect on the left side, and there was dulness below and hyperresonance at the upper part. The heart was displaced to the right. The chest measurement, however, was half an inch less on the left side than on the right. Dr. Bristowe concluded that it was a case of pleurisy with effusion, in which the fluid had been absorbed and the lung had not re-expanded. But this hypothesis did not explain the displacement of the heart. Later on, the measurement of the left side was found to have increased an inch and the area of dulness extended down to the base of the chest, though it had not increased upward. It was then decided to perform aspiration, and the trocar was introduced into the left anterior axillary line. Air escaped, but no fluid. Dyspnœa came on, and the patient died in a few minutes. Post mortem, an hydated cyst was found in the lung, and there was a rent in it of some size by which it communicated with the left bronchus. A similar but smaller cyst was found in the right lobe of the liver. The proper treatment for such cases (when diagnosed) would be a free opening—possibly with excision of part of a rib.

Dr. T. D. Acland said he had had a similar case, but his patient recovered. Dr. Wallis mentioned a case which occurred in the Sydney Hospital, where an hydatid cyst of the lung was being aspirated, and the patient suddenly died after a pint and a half of fluid had been slowly drawn off. It was found that the cyst had ruptured into a bronchus and flooded the respiratory tract. Dr. Sidney Phillips said he had seen a similar case, and had collected records of one hundred and thirty-eight cases. Thirteen of these had been operated on, and four of these had died, but not, apparently, from the operation. He concluded that aspiration could be done without great danger, whereas almost all the cases which were left to themselves (without operation) died. His own patient, after being operated on, had coughed up bits of hydatid membrane together with casts of the bronchial tubes.

The Bradshaw lecture for this year, at the College of Surgeons, has just been delivered by Sir Spencer Wells, who selected as his subject, "Modern Abdominal Surgery." He said that all must acknowledge that the contrast of the abdominal surgery of the early years of the Victorian age with what we might call modern abdominal surgery was very remarkable. An occasional operation for strangulated hernia was almost the only piece of abdominal surgical work done in those days. The radical cure of hernia had scarcely begun to attract attention. Astley Cooper had tied the abdominal aorta, but a case of Cæsarean section, when heard of, was talked of as a marvel both by the profession and the public. A gunshot or other penetrating wound of the abdomen was rarely met with in civil practice, and there, with an occasional formation of artificial anus, abdominal surgery might be said to have reached its boundaries. Neither then nor now had operations on the rectum, nor (until quite recently) removal of stone from the bladder, been classed as parts of abdominal surgery. Sir Spencer Wells proceeded to illustrate in greater detail the advances which have been made, by comparing the survey of abdominal surgery given in Syme's "Principles of Surgery" (1856), with that given in modern works. He then proceeded to speak at some length of his own work in the same field. Ovariotomy, he said, was the starting-point in the modern advance of abdominal surgery, and the first extension was to uterine tumors and to partial and complete extirpation of the uterus.

The lecturer expressed very decided opinions as to anæsthetics and as to drainage in abdominal operations. He regards methylene as the most desirable anæsthetic agent, and said that he had been surprised that, in the face of the reports of deaths from chloroform repeated week after week in the newspapers and medical journals, we had not yet had to defend one of our brethren against a verdict of manslaughter, on the ground that an anæsthetic, well known to be dangerous, had been administered when others, equally efficacious, were known to be safer.

Drainage—with or without "flushing" of the peritoneal cavity—was one of the more recent additions to the practice of abdominal surgery. Sir Spencer Wells said that, in his own work, he had from the first looked upon drainage as a practice to be avoided, if possible, and he had only put in a tube when he knew he had not been able to thoroughly cleanse the peritoneum, or thought that some oozing was likely to go on after the incision was closed, or when, some days later, he suspected the presence of fluid in the cavity. He soon, however, began to think that the tube acted as an irritant, and led to the formation of the fluid which it served to remove. At first, when in doubt, he put in a tube; very soon, when in doubt, he left it alone. More than once he was sorry he had not used it, but much more often he was glad. Only twice had he "flushed" or washed out the peritoneal cavity with warm water, and in both cases he regretted having done so. When the bladder or intestine had been wounded by gunshot, or otherwise injured, and urine or fecal matter had escaped into the peritoneal cavity; or when pus had escaped from an abscess, flushing might secure more complete cleansing than simple sponging, and so become valuable. But in a large majority of cases of removal of abdominal tumors, flushing simply added to the amount of sponging required, at the expense of more or less shock or depressing effect, and left the patient no better, perhaps worse, than after careful sponging with soft moist sponges. He had tried several substitutes for sponges, but had not found anything that answered so well. He preserved them from infective pollution in the manner he had repeatedly described. The lecturer then related in detail three cases which had occurred in his own practice, during the present year, and where he had hesitated as to flushing and draining; for the cases seemed to be exactly the cases where at least drainage was imperatively necessary. All three cases recovered admirably, without either flushing or draining.

A new scheme for the reconstitution of the University of London is being prepared by the senate. It is proposed now to admit representatives from certain provincial colleges, and thus probably avert some of the opposition evinced so strongly to the former scheme.

THE LYMPH TREATMENT IN VIENNA.

(From our Special Correspondent.)

VIENNA, December 21, 1890.

SIR: Though the vital interest in Koch's anti-tuberculous injection has by no means lessened, one is conscious of a perceptible diminution in the excitement which attended the earlier days of its public life. The attitude of the Vienna school on this question has been, from the first, extremely cautious. Although not behind other teachers in anxiety to witness and produce the extraordinary effects described by Koch, there have been here none of the enthusiastic utterances which one heard in Berlin. Prussian sentiment is largely controlled by a *Patriotismus*, which is fostered in every way by the shrewd and able young Kaiser. The idea that a blessing had come to mankind through a German led thus to self-gratulations in which the cold counsels of caution received no attention. Now, however, one begins to hear from Berlin itself questionings and adverse criticisms, and it is not surprising that in Vienna doubts should be quite outspoken.

To begin with, does this injection afford any real diagnostic test of the presence of tuberculosis? This is the question which Professor Maydl asks this week, very pointedly, in the *Klinischer Rundschau*. He relates that he has injected five cases of tuberculosis, all of which reacted; two of carcinoma, both of which reacted very markedly, and six healthy devotees of science who have the honor to be his clinical assistants, of whom three reacted briskly and three not at all. Moreover, the reaction in the tuberculous was often not so intense, nor obtained by so small a dose, as in the non-tuberculous.

These experiences are quite in line with those of other observers. Kaposi reports similarly that at first the reaction followed in the tuberculous almost exclusively, but after further trials, that syphilis, sarcoma, and lupus erythematodes reacted. And from Berlin comes also the admission that there are tuberculous cases which do not react and non-tuberculous cases which do.

It is only just, however, to distinguish between the general symptoms of chill, fever, malaise, etc., which those affected by diseases other than tuberculosis, and even healthy persons, may exhibit in an intense degree, and the local reaction, which, so far as I have seen and can learn, is witnessed only in tuberculous foci. Koch, of course, cannot claim a pathognomonic significance for a general reaction which he describes himself as having experienced in his own person. But I have yet to hear that cancer, or syphilis, or other non-tuberculous local affections have presented those changes which so astonish one observing them for the first time that Sir Joseph Lister, in the last *Lancet*, describes himself as utterly amazed thereby.

We are also learning that the injection is not free from danger. Lublinski reports a case in which a temperature of 41° C., with loss of consciousness, ensued upon the injection of 1 milligr. From Berlin come reports of deaths in private practice and in hospitals. Several cases of pulmonary tuberculosis have succumbed here. Professor A. Jarisch gives this week full details of a case of lupus vulgaris, to which he administered 2 milligr., which produced intense general and local reaction, followed by heart-failure, coma, and death thirty-six hours after the injection. It is, therefore, not without reason that the parental Government of Austria has taken steps to prevent indiscriminate experimenting by physicians at large, and to confine the use of the remedy to hospitals and responsible institutions till its limitations and dangers are more exactly ascertained.

And on the greatest thesis of all, the therapeutic value of the discovery, dissenting voices are also making themselves heard. In the Berlin Dermatological Society Köbner boldly stated that not in one of all the great number of cases (some fifty) of lupus whose treatment he had watched for many weeks, had he, even after thirteen to fifteen injections, seen a cure result. And, though as yet the teachers of most reputation in Vienna are unwilling to predicate anything whatsoever regarding the curative power of Koch's lymph (Billroth said, in my hearing, that he might need a year in which to reach any conclusion), nevertheless, the feeling gains ground that decided change for the better in the cases under observation is, at any rate, very slow in coming. One hears, furthermore, of cases made very much worse, locally and generally, by the treatment, and of others in which fresh tuberculous masses and foci had demonstrably developed while the treatment was in progress.

Such facts tend naturally to destroy the complete harmony and confidence so freely expressed a few weeks ago. There cannot be said to be any consensus of opinion. A shrug of the shoulders is the only reply to questions. All feel that time, probably much time, will be needed before any observer will be warranted in formulating an opinion.

No real cure has yet been obtained here in Vienna. Professor Billroth exhibited a case of lupus some few days since in which active ulceration had ceased, and the site of disease had scabbed over. But whether this indicated any real extinction of the tuberculosis, or was more than a certain reactive, curative effort consequent upon the severe local inflammatory process set up by the injections, he felt himself unable to say. The case of lupus in Professor Hebra's wards, described in my last, which seemed after the separation of the superficial sloughs much improved, is now in about the same condition as at first. Professor Kaposi's cases receive their allotment of Kochine from time to time, present typical local and general reactions, but do not yet heal. Of course, in all these cases time enough may not yet have elapsed. In the meanwhile, after one has satisfied curiosity by repeatedly seeing the scarlatinous rash, the swelling, the oozing, and the incrustations, he is content to await the verdict of time, and to proceed with the ordinary routine of work. This in Vienna is wonderfully varied and interesting, and I shall later endeavor to give some account of the opportunities afforded.

TENEMENT-HOUSE SCHOOLS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Now that the school question is so much in the public mind, I would like to call the attention of the proper authorities, through your esteemed journal, to the existence of certain tenement-house private schools, in the lower part of our city, which are not conducive to the best interests of health and morals, no matter how beneficial they may be to the youthful mind. I refer to the schools for instruction in Hebrew in the Russian-Polish-Jew settlements. These are usually located in the dwelling-rooms of dilapidated rear tenements, where, in the first place, the air is not fit for the family itself to breathe, much less for a crowded roomful of growing boys. Secondly, in the family of the Rabbi, or teacher, contagious diseases frequently occur, and subject not only the whole school to danger, but the community at large. Thirdly, these growing children are placed in the midst of sights, smells, and surroundings which do not tend to elevate them, and are often physically deleterious.

Yours truly,

CHARLES W. ALLEN, M.D.

NEW YORK.

THE TRANSFIGURATION CLINIC.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the MEDICAL RECORD of December 13th, page 670, I notice the following statement as regards the Transfiguration Clinic: "It is intended only for the poor of the parish."

Permit me to correct this. The Clinic is designed to furnish medical attendance and assistance to all de-

serving poor, whether of the parish or not. While under the direct control of the church, the desire of the promoters is to have the deserving poor receive the same thorough care that would be extended in a physician's office, and not the usual perfunctory attention of a dispensary, necessarily limited by the great number of cases and the limited time at the disposal of the physicians. Another feature of the Clinic is in the supplying of medicines. No medicines are kept on hand, but a prescription like any private prescription is given. This is then taken to a neighboring druggist, with whom an arrangement has been made, who prepares the medicine and sends the bill to the Clinic. By this means remedies applicable to special conditions are secured, and not what is too often the case, Nos. 1, 2, or 3 given because already prepared, or because of a necessary haste from a large attendance. Yours respectfully,

EDWARD QUINTARD.

NEW YORK.

RACIAL IMMUNITY AND INOCULATION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your editorial entitled "The Pathology of the Blood," in your December 20th issue, has a special interest for me, as I have given much thought to the same question, and even believe to have gone a step in advance of what is suggested in your article. Instead of transferring the immunity from animals to man, I have thought of an experiment in which I should try to transfer it from man to man. You know how much I am interested in some pathological conditions of the country where I have spent a few years of my life. Your observations give me an opportunity to communicate some ideas which you will perhaps find interesting in connection with the subject in hand. The question of Japanese immunity from scarlet fever has received much attention from European observers. The general opinion is that the disease never existed among Japanese, and was known in the country only among foreign residents as an imported calamity, even then without danger of contagion to the natives. This being the fact, it has occurred to me to make a few experiments in order to find out whether it might not be possible to obtain something reliable in the way of security for Europeans in their own countries, by reinoculating them with the disease after its inoculation into the Japanese. I did not obtain from my first experiments any result worth mentioning. I had, last September, inoculated a Japanese with scarlet-fever germs without communicating the disease, but I shall soon inoculate a half-breed with scarlet-fever virus. If the disease is transmitted at all, we have a right to expect to find it modified, and then it will remain to be seen whether the immunity of the privileged can be in any measure communicated to the non-privileged race.

As the question of the mixing of races is probably closely connected with my present subject, you will perhaps find that the following quotation from Quatrefages ("The Human Species") is not entirely out of place: "The crossing," says the French savant, "although apparently left to chance is in reality unilateral and always directed toward the superior race, and is accomplished under the influence of a real unconscious selection, and the predominance of the white blood is the result of this selection. Sooner or later it will result in the fulfilment of the prophecy of Martin de Moussy. The mixed races will in a great measure return to the superior race. But when brought back to the white type by this circuitous path, and through all these degrees of crossing, they will possess one very great advantage over their European counterpart, they will be acclimatized."

The latter assertion, however, is still considerably open to discussion. It must be admitted, besides, that scarlet fever belongs to that class of diseases whose exact nature is still undetermined. Simmons alone, of foreign observers, it is true, says: "The absence of scarlet fever from Japan may be due to its being mostly below the isothermal line of the disease elsewhere." Thus it appears that there is some authority for assuming that the immunity in question is due to a climatic rather than a racial factor. But, as already stated, this is, in point of authority, all which those who should assume that the immunity in question is due to a climatic rather than a racial factor, have to stand on.

The same author (Quatrefages) says further: "The victory of the superior energies is shown in another very remarkable manner in the crossing of white and black races. The former (the white) is of all races most sensible to malarious influences, the latter (the black) best able to resist them. On this account the black race is almost exempt from yellow fever. The mulatto inherits this double resistance (that is, of the black race to malarious and yellow-fever influences). Dr. Nott assures us that a proportion of one-fourth of black blood is as sure a protection against yellow fever as vaccination against small-pox."

This fact of the resistance of the black race to malarious and yellow-fever influences is admitted in some degree by the profession generally, although not so absolutely as Quatrefages would have it.

However, these limitations being acknowledged, it remains still an undoubted fact that plasmodium malariæ is not readily developed in the blood of the black race (nor is scarlet fever); this may be due to the protection afforded by the skin-pigment against the influences of the climate. It may be also that the blood-corpuscles of the black race are less subject to yellow fever or other disintegration. But let this, too, be considered as an open question. Certainly the difficulties which stand in the way of the acclimatization of certain races in countries which enjoy some natural immunity have much to do with their developing certain diseases. On the other hand, whether the complete acclimation of a new race in a favored country can endow it with the natural immunity possessed by the natives, for instance the European resident with the Japanese immunity from scarlet fever, remains still to be learned.

I hope to resume the line of experimentation of which I have spoken above—I mean the attempt to transfer the natural immunity of one race to the other by blood inoculation—under the most favorable circumstances, for I hope to be in Japan next spring, and to have every element and means of inquiry in my reach.

Yours most faithfully,

ALBERT S. ASHMEAD, M.D.

4 KING STREET, NEW YORK.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 28, 1890, to January 3, 1891.

WAKEMAN, WILLIAM J., Captain and Assistant Surgeon. By direction of the Secretary of War, relieved from the further operation of Par. 13, Special Orders No. 254, A. G. O., October 30, 1890, and telegraphic instructions of the 16th instant, from this office, transferring him from Fort Bidwell, Cal., to Fort Huachuca, Ariz. Ter.; and he will return from Reno, Nev., to Fort Bidwell, for further duty at the latter post. S. O. 300, par. 3. A. G. O., Washington, D. C., December 24, 1890.

RAFFERTY, OGDEN, First Lieutenant and Assistant Surgeon. By direction of the Secretary of War, relieved from duty at Fort Sam Houston, Tex., and will report in person to the Commanding Officer at Camp Eagle Pass, Tex., for duty at that station, reporting by letter to the Commanding General, Department of Texas. S. O. 301, par. 2, A. G. O., Washington, D. C., December 26, 1890.

COWDREY, STEVENS G., Major and Surgeon. By direction of the Secretary of War, the extension of leave of absence on account of sickness, granted in Special Orders No. 293, December 16, 1890, from this office, is still further extended one month, on account of sickness. S. O. 302, par. 8, A. G. O., Washington, D. C., December 27, 1890.

LAUDERS, JOHN V., Major and Surgeon, now on duty at Fort Ontario, N. Y. By direction of the Secretary of War, will proceed without delay to Pine Ridge Agency, S. D., and report in person to Brigadier-General John Brooke, for duty in the field, and by letter to the Commanding General, Department of Dakota. S. O. 303, par. 8, A. G. O., Washington, D. C., December 29, 1890.

KILBOURNE, HENRY S., Captain and Assistant Surgeon; GARDNER, EDWIN F., Captain and Assistant Surgeon; and EVENTS, EDWARD, Captain and Assistant Surgeon. By direction of the Secretary of War, the above-named medical officers will proceed without delay to Pine Ridge Agency, S. D., and report in person to the Commanding General, Department of the Platte, for duty in the field. S. O. 304, par. 9, A. G. O., Washington, D. C., December 30, 1890.

Official List of Changes in the Medical Corps of the United States Navy for the week ending January 3, 1891.

PICKRELL, G. McC., Assistant Surgeon. Detached from the Minnesota, and wait orders.

MCCORMICK, A. M. D., Assistant Surgeon. Ordered to the Minnesota, as Dr. Pickrell's relief.

AN INTERNATIONAL CONGRESS OF MICROBES AT BERLIN.

By GOUVERNEUR M. SMITH, M.D.,
NEW YORK.

MICROSCOPICAL midgets
Were getting the fidgets,
On hearing the horrible news,
That the microbes were slaughtered—
Were starved and were quartered,
'Twas surely a cause for the blues.

Smallest plants and wee bugs
Are not dull, snail-like slugs,
But form a unicity rare;
They commune with each other
(Each kingdom, a brother)
When both have a terrible scare.

So an edict went forth
East and West, South and North,
For the Microbes in Congress to meet
In the place, where a sage
Who is now all the rage,
Thinks such elfins—each one—a dead beat.

A great polyglot crowd
Of wee Liliputs proud,
Assembled in solemn conclave,
And those speaking Phthisis
With warm exegesis,
Besought all their friends to be brave.

Then one spoke in Lupus,
With tones base and croupous,
And said he was "not a bit blue,
I'm not yet like Othello—
And will fight a duello,
With Koch or some one of his crew."

A tenor, in Typhoid,
With gestures quite cycloid,
A tiny Professor,—then said
"On mankind I'll still sup,
I won't give his flesh up,
And of starving I'm not yet afraid."

A speech in harsh Cancer,
By a wise geomancer,
Foretold of a bright coming time,
When no more on the earth
Would there be human birth,
As the microbes were just in their prime.

And with man quite extinct,
It was clearly distinct
The Germs would then evolute gay,
Be lords of creation—
The great innovation,
At which Time was now making a play.

In Cholera lingo,
One said that,—"By jingo
Men eat their choice game with suave grace,
We'll feed on their flesh-pots,
These devilish despots,
Until we have eaten their race."

In co-operation
These dwarfs of each nation
In solemn alliance agreed,
"Fierce aggression, severe,
More and more every year
Till the earth of mankind was quite freed."

They adjourned for a dance
In high glee and joyance,
And whirligiged round like young nymphs:
In Koch's parlor so gay
They danced a whole day
And laughed at his new-fangled lymphs.

Then they wound up the fête
With a feast quite ornate,
Consuming wise doctors, a score,
And drank their own health
In the lymphs, got by stealth,
And wished they had kegs and kegs more.

An Evidence of Cure.—Dr. S. Weir Mitchell, of Philadelphia, is said to have recently received from a female patient the singular present of a cord of white-oak wood, chopped down and sawed up by her own hands. He had recommended to her an active out-door life in the woods for nervous invalidism. She had followed his directions, with results of which the cord of sawed wood was one of the evidences.—*Boston Medical and Surgical Journal.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 3, 1891.

CHANCRES OF THE FINGERS:

THEIR CLINICAL HISTORY, THEIR COMPLICATING SEPTIC INFECTIONS, AND THEIR DANGER IN SURGICAL AND OBSTETRICAL PRACTICE.[1]

BY R. W. TAYLOR, M.D.,

CLINICAL LECTURER ON VENEREAL DISEASES AT THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

I ESTEEM it an honor to be asked to participate in the exercises of this, the first meeting of this new section of the Academy, and I take pleasure in reading this essay under the auspicious circumstances which surround it, and under the presidency of my old-time friend and colleague, Dr. Otis.

It has long been apparent to me that there is need for an essay which shall contain in concise form a systematic description of the lesions produced by syphilitic infection upon the fingers, and to fill this gap in medical literature I have, from time to time, jotted down observations and have recorded the clinical features of such cases over a period of many years. As a result, I think that the clinical divisions which I have made of chancres of the fingers will be found to be correct and sufficiently sharply marked, and that they will aid the reader in many puzzling cases. It must be understood that although the objective features of these chancres differ widely, the underlying pathological process is really the same in all. A consideration of the various modes of finger-infection is naturally called for by the scope of the paper. Next in importance in this study is the rôle played by acute septic infections when complicating finger-chancres, and lastly, the dangers inherent in these lesions when present on the hands of surgeons, obstetricians, and physicians, needs prominent emphasis.

Chancres of the fingers contracted in operations, examinations, and manipulations are not uncommon among obstetricians, surgeons, and midwives, and they are occasionally seen upon the hands of some luckless laymen as the result of their handling or lascivious fondling the infected genitals of some female. They are also observed in dentists, contracted in operations on the mouths of syphilitic patients. They may be seated upon the finger-pulp or around the nail. Syphilitic finger infection has been seen in children and women as a result of picking or dressing the hard chancre of a second party. Finger chancres as a result of a bite by a syphilitic person are also occasionally seen. Chancres of the knuckles and fingers have been known to follow a blow delivered upon the mouth of a person suffering from specific lesions.

These chancres are prone to form at some part of the nail margin, also on the sides and on the pulp of the finger and along its continuity. In the greater number of cases they are due to the infection of a small fissure, a chap, an excoriation or a cut, or to the lodgement of the virus between the nail and its tegumentary fold. Any skin disease of an inflammatory or hyperplastic nature situated upon the fingers or hands may afford a port of entry for syphilitic infection. I recently saw a formidable chancre upon the finger of an eminent surgeon, which resulted from the infection of a spot of eczema, which was caused by the carbolic acid or bichloride solutions used in his operations. The significance of this fact should be remembered by surgeons generally.

My studies and observations convince me that for clinical purposes we may divide chancres of the fingers into four forms, as follows: 1, The scaling papule or tubercle; 2, the excoriated or exulcerated nodule or mass; 3. the fungating chancre; and, 4, the panaritium-form chancre. The water colored drawings which I shall show will materially aid my hearers in a clear understanding of the subject.

1. The Scaling Papule or Tubercle.—This form of digital chancre is the mildest and simplest in character, and is the rarest of all forms observed on these members. It is usually found upon the dorsal surface of a phalanx, and exceptionally it is seated upon the palmar surface or the sides of the fingers. It usually begins on the site of a slight cut, an excoriation, or a fissure. The traumatic lesion may or may not heal and disappear. The chancre begins as a small red spot, which may or may not be scaly. This spot usually grows quite promptly, and in about a fortnight a round or oval papule or papulo-tubercle is formed, having a diameter of half an inch more or less. Thus fully formed the lesion may be of a dull coppery red, occasionally of a bright rosy red, and also of a dull purplish hue. It may thus remain in an indolent slightly scaly state, or it may extend. Whenever the morbid process extends and reaches the wrinkled skin over the joints, fissuration is liable to occur, and this complication may be the starting-point of an ulcerative process which may involve the whole extent of the chancre. In this event this lesion may assume the characters peculiar to the two following forms of digital chancre. Then, again, owing to any traumatism, such as friction, blows, washing, chemical irritants, heat and cold, the chancre may, even when not impinging on joint surfaces, become excoriated and ulcerated. In its uninflamed state the scaling digital chancre runs a chronic, uneventful course, and causes little uneasiness, and not much inconvenience. It thus often happens that its serious nature is not suspected, and frequently the diagnosis is not made until the evidence of lymphatic hyperplasia or of secondary manifestations makes it clear. The scaling papule may exist for weeks, or two or three months, and then it sinks down and disappears, leaving a thickened, more or less purplish or brownish-red pigmented site, which may or may not be the seat of induration or of more or less atrophy. (See Fig. 1.)

2. The Excoriated or Exulcerated Nodule or Mass.—This form of digital chancre may be said to be the most common, and it has well-marked features. It is usually found toward the end of the finger, and to have its origin in some lesion of the nail margin. This may be an excoriation or fissure, a hangnail, or even some slight separation between the skin and the nail inappreciable to the naked eye. The original wound frequently heals, but in some cases it remains open and indolent until the advent of the syphilitic process.

The exulcerated nodule of the fingers usually begins as a small pustule or as a minute, red excoriation of varying shape. This latter lesion increases quite rapidly in area and in height, and is, in its early days, indolent and painless. It may reach only to small size, but usually the hyperplasia is luxuriant. Full development may occupy a period of two to four weeks. We then find a large, fleshy, smooth, granular, or even

[1] Read before the Section on Genito-urinary Surgery of the New York Academy of Medicine, December 9, 1890.

lumpy mass, of a dull red color, sometimes with a purplish tinge, which, to examination, reveals a condition of firmness but not of decided induration. Then, again, in some cases this chancre is rather soft and flabby. The shape of the mass depends on its situation. If seated on one side of the finger it may jut out from one-half to one inch. If both sides of the finger (and in this event the whole margin of the nail is usually the starting-point) are involved, the mass may become as large as a horse-chestnut. It may or may not give to the finger the shape of an Indian club. The course of this chancre depends entirely upon the manner in which it is treated. If kept free from irritation and at rest, it will slowly subside, but if irritated its duration is indefinite. Cases are known in which these chancres have existed for nearly a year. I have seen one such instance. Their chronicity is an important matter, for it carries with it dangers of infection to others.

Under treatment the excoriated nodule gradually becomes the seat of healthy granulations, which wither and contract with or without suppuration (which may be prevented by antiseptic treatment) until a scar or a dense fibrous, perhaps indurated, mass is left. These chancres are, as a rule, followed by more or less deformity. In some cases the nail is wholly destroyed, or the destruction may be partial, and may be replaced by an imperfect new-formation. There is usually more or less destruction of the nail margin, and very often the distal phalanx is left in a distorted or shrivelled state. When originating in the sulcus under the free margin of the nail these chancres may lead to the loss of the tactile pad of the finger, and to a conical, slightly shortened state of the organ. Besides the unsightliness of the deformity, this sequela is to be regretted by reason of its impairment or abolition of the tactile function. In some cases tenderness and pain are complained of for long periods, and mild phlebitis and lymphangitis may for a time be present. Then, again, pain of a very severe and persistent type is often observed during the course of this chancre. (See Figs. 2 and 3.)

3. The Fungating Chancre.—This form of digital chancre is a not uncommon one, and begins in a moist or dry red spot, or a pustule upon the seat of some traumatism, and is most commonly found toward the tip of the finger. Usually the lesion pursues a mild and subacute course for a week or two, being simply a large or small excoriated or exulcerated nodule, as already described. Then generally, as the result of some irritation, but also from conditions inherent in the chancre process, granulations begin to spring up and the surface of the chancre becomes fungating. This appearance may consist in a condition to which we would ordinarily apply the term profuse granulations, or it may be of a decided fungoid character. The granulations are then very large and very long, and it is usually to be distinctly seen that they, after springing from their base, become separated from one another by a distinct but small interval. I have seen them as long as one-eighth of an inch or of one-sixteenth of an inch, and even longer. They look like digitate processes, and resemble, though slightly, in shape, but not in color, the verruca digitata. They may also resemble in some cases condylomata lata which have become vegetating. To the touch these fungating chancres are not very firm or resistent, and they may even be soft, boggy, and compressible. They are usually of a dull bluish or purplish red color, and I have seen them of a pale gray, or of a gray tinged with blue or lilac color. As a rule, no evidence of the existence of blood-vessels is to be seen in their structure. They are most exuberant and fully developed when springing from the pulp of the finger, and may be seen in a lesser size around the nail margin, and even on the sides of the finger. These fungating chancres sometimes run an indolent course, showing little, if any, tendency to healthy action, and then again they are observed to become the seat of rapidly exuberant growth, which shows a persistency to recur even in spite of active cauterization or destruction. Under proper treatment they sink down and wither, and give place to a healthy healing surface. There is commonly more or less deformity left by these chancres. Either the nail is more or less permanently destroyed or a retractile and perhaps fibroid red or purplish-red scar is left which constitutes a permanent deformity. As a chancre progresses toward a cure (and not before this date) the condensation of the tissues may give rise to a condition of firmness, perhaps, resembling induration. In none of these chancres, however, do we find induration such as is observed upon the penis. Pain of a mild, and even of a severe type, is a not uncommon symptom, and it is frequently noted to appear during an exacerbation of the fungoid process.

Phlebitis and lymphangitis of a mild, even decided type, may be an accompaniment of this chancre at some period of its existence. (See Fig. 4.)

4. The Panaritium-like Chancre.—This form of chancre of the finger is not very common, and is seen with rather more frequency than the scaling chancre of the fingers, and less frequently than the ulcerated nodule or the fungating mass.

The panaritium-like chancre of the fingers usually begins in the integument of the nail margin or in a cut, a fissure, a hangnail, or in some simple inflammatory lesion, very often as a pustule. Whatever may have been the medium of wound-infection, it usually heals quite promptly, unless irritated, and in due time after incubation the chancre appears as a red spot, which may or may not be excoriated. This spot soon assumes greater depth of color and of development, and subacute inflammatory infiltration begins, which confines itself pretty closely to the nail sulcus, along which it creeps and develops. The result is that appearances resembling a simple tegumentary felon are soon seen. With the increase of the specific perionychia the distal phalanx begins to swell and the finger becomes distorted. During this period of invasion pain of a mild or severe, deep-seated, and even throbbing character, is often complained of, and the use of the affected finger is impaired or abolished. Usually the swelling increases until the end of the finger presents a bulbous shape like an Indian club, or it may present a shape like a tulip or a violin. The redness, which was at first bright, gradually becomes darker, until in full development the chancre presents a dull brownish-red hue. As the hypertrophic process increases ulceration is usually seen around the nail, to which it may be limited in a crescent-like form. This ulceration usually has an unhealthy, foul surface, secretes a copious, fetid pus, and may be covered in whole or in part with a brownish black or green necrotic film or membrane. The nail rapidly becomes darker, until it is detached as a black looking, foul mass, under which the ulceration has extended. At this time the pain is very severe, the swelling very considerable, and the consistence of the hypertrophied phalanx very firm, and sometimes even hard. There is nothing akin in it, however, to cartilaginous induration. There may or may not be redness in the skin of the second and third phalanges. In this state of full development this panaris-like chancre may remain for a long period without any tendency to heal, and sometimes without any evidence of exacerbation. Under proper treatment, however, it will slowly subside, and in the course of several months the end of the finger may be nearly normal in size. Sometimes it becomes much atrophied and pointed, and the seat of an irregular cicatrix. In most cases the nail is impaired, sometimes wholly destroyed, and sometimes only partially so. Tactile sense and prehension are more or less impaired, and an exquisite tenderness may remain in the member for a long time. This form of finger-chancre may be mistaken for non-specific panaritium, and for the early and later perionychiæ of acquired syphilis. In hereditary syphilis a perionychia presenting points of resemblance to this form of chancre is occasionally seen. Accompanying the

panaritium-like chancre a mild or severe phlebitis or lymphangitis may occur. In all cases a doubt in diagnosis can soon be cleared up by the examination of the epitrochlear and axillary ganglia, which commonly within two weeks take on characteristic syphilitic swelling and induration. One finger is usually affected by this form of chancre, sometimes two, and very rarely more.

Occasionally the chancre is limited to one-half of the nail margin, as shown in the water-color drawing I now show. The epitrochlear and axillary ganglia are always very much enlarged and hardened. In some rare cases the indurating process seems to skip past the epitrochlear ganglia, and to expend its intensity upon the axillary group. Fig. 5 shows a chancre which involved the whole nail margin, while in Fig. 6 only one half of the nail is seen to be affected.

Phlebitis and lymphangitis of a mild form and short duration, attended with a sense of sickness, malaise, and elevation of the temperature, are not uncommon concomitants of digital chancres. These inflammatory phenomena are usually the result of irritation or bruises of the fingers, or of dirty particles which have become lodged upon the chancre.

In exceptional instances true pyæmic and septic infection may complicate the course of digital chancres, as shown by the following cases:

Case I.—An Irishman, a handler of hides, aged twenty-two, a man of dissipated habits, but strong and robust, came under my observation in 1870, with a chancre of the right index-finger. When first seen this lesion was simply a small exulcerated nodule situated on the left side of the nail at its base. A carbolic ointment was ordered. In two weeks, during which the man kept busily at work and applied the ointment imperfectly and irregularly, he returned, and I found a large, fungating chancre of bluish-red color, which secreted a thin, sanious, and fetid pus. He was urged to leave off work and to apply a lotion regularly and liberally. This he failed to do, and went off upon a drunken spree. At the end of this period, which occupied a week, the chancre remained stationary, and he returned to his work. When next seen, some days later, this man presented the following symptoms: He was suffering from recurring chills of a severe type; his pulse was rapid and small; he complained of pains in the legs and head; showed evidences of prostration and a pinched, dejected look; had no appetite, and suffered from diarrhœa. He had been sick in this way four days, his illness being ushered in with severe pain in the affected finger, running up the forearm and arm, a chill of marked severity lasting an hour, and great malaise. I found the chancre of the finger to present a very unhealthy appearance; its surface was much swollen, covered with a dirty necrotic tissue, and a thin, fetid pus. The whole finger was of a dusky red color and much swollen, and evidences of phlebitis and lymphangitis could be seen in the red lines running up the inside of the forearm. For a week the temperature ranged between 102° and 105° F., with febrile symptoms in full accord. The local treatment consisted in thorough cleansing of the chancre, long continued immersion of the hand in very hot and mild alkaline water, and the application of a carbolic solution on lint. Internally quinine, alcohol, and nutritious fluid food were given. Under this medication, local and general, the fever began to abate on the seventeenth day, and the man entered upon convalescence. He was away from his business for twenty-four days, during which the condition just described took place. I feared that suppuration would occur in the epitrochlear and axillary ganglia, but though there was very great swelling in them, it, in course of time, subsided. One month after recovery from this pyæmic attack, secondary syphilitic symptoms of a severe type appeared. My calculation made at the time was that the acute infective process delayed the evolution of the symptoms of the chronic infection, namely, syphilis, rather more than thirty days. The subsequent course of the syphilis was severe.

In this case the existence of syphilis was quite clear at the first examination, for the reason that there was a distinct history of swelling and ulceration of the finger of a subacute type, which, to anyone versed in these matters, was clear evidence of syphilis.

Case II.—In 1875 I was asked by a medical friend to see a medical student, aged twenty-one, of thin and wiry build, and of good habits, who was suffering from a painful ulcer of the left index-finger, and symptoms which he regarded as indicative of typhoid fever. I learned that the digital ulcer began in an insignificant manner about four weeks previously, and that a week before my visit it had become much inflamed and very painful, and that the finger had swollen to a very large size. Soon after this local disturbance the young man had a severe chill, which was followed by a profuse sweat. Then such adynamic symptoms as utter prostration, rapid and small pulse, great dyspnœa, total anorexia, and diarrhœa, soon supervened. In this state chills of short and long duration, mild and severe, were complained of, and the subsequent sweat after each left the patient worse off than before. The temperature ranged between 102° and 105⅗° F., the tongue became dry and cracked, and there was at intervals a mild delirium. This state of affairs lasted ten days, toward the end of which the symptoms slowly ameliorated. The chills first ceased, but the fever kept on for some days afterward. During this time a large abscess formed, just over the left epitrochlear region and in the axilla. They, when incised, gave issue to an abundant, unhealthy, curdy pus. The local treatment of the diseased finger consisted in long-continued immersions in very hot carbolic acid water, the careful cleansing of the chancre, and the application of iodoform. In this case the evolution of the secondary symptoms was delayed, according to my calculation, fully forty days.

No reason could be assigned by the patient for the onset of the inflammatory symptoms in the chancre, except perhaps, an undue use of the finger. My impression at the time was that the chancre became irritated owing to the want of regular and careful dressings. In this case, also, there could be no doubt from the beginning that we had to do with a case of syphilis complicated with pyæmia.

Case III.—A woman, thin and pale, and of feeble texture, contracted a chancre on her right index-finger from dressing the penis of her lover, who was suffering from a phagedenic hard chancre. The infection-wound took place upon a deep scratch made with a pin along the side of the nail. The first symptoms complained of were throbbing pain and tension in the affected part. Within twenty-four hours great swelling, heat, and redness were noticeable, and a marked condition of malaise and dejection supervened. Then it was noted that a spot the size of a pea at the side of the finger was of a dull, bluish-black color, and the seat of profuse, flabby, and dry granulations. The patient had a severe chill, which was not followed by a sweat, but by a high fever. This ranged between 102° and 105° F. for several days, and was accompanied with great prostration, dyspnœa, utter want of appetite, and the usual concomitants of a typhoid state. Within thirty-six hours after the invasion of the finger the hand and arm swelled to an enormous extent, became very red, tense, and painful, and all along it deep red lines were to be seen. The patient suffered much agony and presented an anxious, drawn look. She was very sleepless, and prone to fall into little periods of mild delirium. In this state she remained for ten days when improvement was noted. The swelling and pain in the arm became less severe and marked, and the temperature fell to nearly the normal standard. Ten days more elapsed before the patient could leave her bed, and then she was weak and much thinner than before the attack. At this time the wound on the finger-tip, which had been large, fungoid, and exuberant, looked like a little thickened excoriation, and the epitrochlear and axillary ganglia were very much enlarged. Gradually the finger wound developed into a typical exulcerated chancre, which was

followed by general syphilitic manifestations about eighty-six days after the date of the wound-infection.

In the days when these cases were observed we knew nothing of surgical bacteriology, and I was much puzzled by their peculiar course and symptomatology. To-day their nature, and that of their complications, are tolerably clear.

In Cases I. and II. there can be no doubt that pyæmic infection occurred in the finger-lesion of the chronic infection, namely, syphilis. It is probable that the agent of infection was the streptococcus pyogenes of Rosenbach. Where the first patient picked up this micro-organism I cannot say. He handled wet hides and was careless and dirty in his habits, and was given up to a debauch for fully a week. In some way "lumps of dirt," as Lister terms them, must have gained access to the diseased tissue forming his chancre.

In the second case no history of contamination could be obtained, but the origin of the pyæmia was undoubtedly somewhat like that of Case I. In these cases the micrococci found pabulum, or a culture-ground as we may say, in the diseased tissues of the finger. Multiplying, then, in vast numbers, they permeated the small veins, there produced an infective phlebitis and a thrombus, which, in their turn, by exuberant growth and development, produced the secretions and microbes which, carried by the vessels, poisoned the whole system. The radical antiseptic treatment of the finger-wounds undoubtedly led to the destruction of the pyæmic foci and the ultimate rescue of the patients. I need not emphasize the course of the pyæmia in these cases, for it was typical in both, and as such cases go it may be said to have been tolerably mild. The patients were confined to bed from two to four weeks.

The interesting fact is brought out by these cases that the evolution of the syphilis was considerably delayed, even to the extent of about one month in the first case, and forty days in the second. This delay in the evolution of secondary syphilis has been noted many times as being caused by intercurrent acute diseases.

The history of the third case is interesting and peculiar. In this case there was no pre-existent chancre, but syphilitic infection and septic infection took place simultaneously through the entry of the secretion of a phagedenic chancre into a minute healthy wound on the woman's finger. In this case the symptom-complex points to a mild form of septicæmia, for there were no chills after the prodromal one. The septic infection began at once, and its effects were well-marked within thirty-six hours. The evidences of general syphilitic infection were rather slow in appearing, and it is fair to assume that they were delayed about a month by reason of the acute septic infection. It is important for surgeons to bear in mind the possibility of a double infection in cases of wounds of the fingers or hands.

I once saw a male patient, a sampler of sugar, aged twenty-eight, who, while suffering from a fungoid digital chancre, had for a day or two great pain, redness, and œdema of the arm, with high temperature and malaise. Under treatment these complications rapidly subsided. The history of this case would seemingly go to show that in digital chancre we may have mild pyæmic attacks, while the preceding ones prove that we may have very severe infection. The possibility of complications so severe as those just detailed should never be forgotten, and surgeons, in treating patients suffering from digital chancres, should be careful to employ thorough antisepsis, and to see that no particle of dust or dirt or foul secretion be allowed to reach these lesions of the fingers.

It is very probable that the softness and sponginess of the tissues so often found in chancres of the fingers is the underlying cause of septic infection. In most instances the syphilitic chancre is firm, and under it a compact, hard œdema is situated. In these cases there is little, if any, chance for the invasion of these pyogenic and septic microbes, for a barrier is interposed which contracts the small vessels and lymphatic spaces, and limits the malign influence to the tissues above them. It is undoubtedly this hard œdema underneath hard chancres, upon the penis and vulva which prevent, in many cases, intercurrent general microbic infection. The superficial, and even deep destructive, effect of micro-organisms upon syphilitic lesions is daily seen, not only on the skin but on the mucous membranes. Therefore I am led to think that the peculiarity of the tissues of the fingers and the want of closeness and compactness of structure of the initial neoplasm of digital chancres (which quite often occurs) are the essential causes which offer a possibility of pyæmic or septic infection.

The fact of the not uncommon occurrence of chancres upon the fingers of surgeons, physicians, and midwives suggests to us the danger of syphilitic infection to their patients. Cases of syphilis transmitted by finger-infection in medical and obstetrical practice are sufficiently common and well attested to warrant us in a consideration of the question of prophylaxis. This subject was prominently brought forward last year by a certain Dr. S.,[1] in a letter, in which he says that it is desirable to know how far physicians, general and special surgeons, and obstetricians, themselves the subjects of syphilis, may be dangerous to their patients, and in how far they should be restricted in their practice. Dr. S. claims that the dangers of syphilitic transmission from an infected medical man to his patients are greater than in married life, the husband or the wife being syphilitic. In reply to this letter,[2] Neisser published a short address, in which he emphasized the main points of danger in a clear manner.

It is evident that surgeons afflicted with syphilis are much less liable to infect their patients than obstetricians, particularly in these days of thorough asepsis and antisepsis. With the care which surgeons give to the perfect cleansing of their hands before operations, and with the fear in their minds (which is quite widely spread) of receiving syphilitic or other infection through any lesion of continuity, in the event of their having a chafe, a fissure, or any suspicious sore or hyperplastic papule, nodule, or mass on the fingers, will, I think, cause them either to give up the operation, or take measures for the thorough protection of their fingers. Then, again, the profuseness with which antiseptics, fluid and pulverulent, are used in operations, will undoubtedly do much to prevent syphilitic infection. Still, I may add that I have often wondered when physicians, afflicted with syphilitic finger-infection, have told me of their multifarious ministrations to their patients, tendered while yet ignorant of the nature of their own disease, why it was that so few cases of such professional infection occurred. Neisser says that he knows of four infected assistants who kept on with their professional work notwithstanding their finger-chancres.

The period of greatest danger from finger infection by medical men is in the early days of the chancre, when it is small (like a chafe, a fissure, a mildly excoriated papule, or seemingly like a simple but troublesome hangnail, or a mild form of panaritium), and when its nature is not suspected. In this period (as a general rule) it is very little, if at all painful; it has not an angry or an inflamed look, but, on the contrary, presents a benign, even insignificant, appearance. In this stage, luckily, its secretion is very scant, and to this fact, therefore, many instances of immunity are undoubtedly due. But even under these circumstances the tissue-elements may be deposited from the infected finger upon a wound in the patient, and syphilis may ensue. Then, again, these seemingly mild lesions may give issue to blood, which, if deposited upon an excoriated, exulcerated, or cut surface, may convey the syphilitic poison. Though syphilitic blood infection is less prompt, active, and constant than infection from primary and secondary secretions and lesions, its danger should always be remembered, feared, and provided against.

[1] Anfrage an die Herren Fachgenossen, Centralblatt für Chirurgie, No. 13, 1889.

[2] Dürfen Syphilitisch-inficirte Aerzte ihre ärztliche Thätigkeit fortsetzen, Centralblatt für Chirurgie, No. 39, 1889.

Chancres of the fingers in professional men usually cease to be dangerous to their clients when they have reached their full development. When they have come to present the features depicted in the clinical part of this essay (if not before), they cause so much pain, so much anxiety, and even horror, that even if they are not considered to be of syphilitic nature they are recognized as formidable lesions and dangerous to others. I have often wondered why many physicians and surgeons who have consulted me have remained so long in ignorance of the syphilitic nature of a finger chancre, and why it has not been recognized by their fellow-practitioners, to whom they have applied for diagnosis and treatment. I think that it will be generally found when a surgeon, physician, or obstetrician, or dentist, has a chronic, indolent aphlegmasic ulcer or nodule on his finger, particularly when near its tip, the lesion is, at least in the majority of instances, the forerunner of syphilis, especially if it has a bluish fungoid appearance, or the look of a piece of raw beef stuck on the finger end. Yet very many think that they are the victims of some obscure form of blood-poisoning, or of tuberculous infection. I have found many physicians whom it was very difficult to convince that they had syphilis. Then, again, I have sometimes observed that when a diagnosis of syphilis has been made in his case, the medical man often makes a tremendous hue and cry. It is this over-anxiety, I have no doubt, which some years ago led to the adoption of a quite prevalent opinion that professional syphilis was particularly severe and intractable in its course. Medical men make bad patients in any form of sickness.

The foregoing facts indicate very forcibly the duty of the physician and obstetrician to refrain from touching his patients, performing operations, making examinations, or giving aid in childbirth if he has any lesion, however mild, upon his finger or fingers.

Among the poorer classes midwives are very extensively employed in childbed, and these women, from ignorance and cupidity, have been known to cause many cases of syphilis. It is difficult to devise means for the prevention of this terrible accident, for these women are not subject to registration and surveillance, and they cannot well be reached by law. They, if brought to bay, contend that they do not presume to undertake medical duties and practice, but that they act merely as nurses. If found attending a case of labor they have been known to claim that they were not acting on their own responsibility, but that they were temporizing and awaiting the arrival of a belated, or absent, or hard-to-find physician. Of late years I have not heard of a case of syphilitic infection transmitted by a midwife, but such a method is well known in Europe to have occurred several times.

The following sad history will carry with it a painful lesson :

A number of years ago I had under observation a whole family who became infected with syphilis through the finger of a German midwife, who had a chancre on her right index-finger. This family consisted of the father and mother and four children, three girls and one boy. The wife had severe ulcerative lesions in the region of the fourchette, and the husband had three chancres of the prepuce and glans, while both suffered severely from buccal mucous patches and condylomata ani. The eldest girl, aged twelve, had a large chancre of the left cheek; the second girl, aged ten, a chancre of the lower lip; and the third child, a boy, had a panaritium-like chancre of the left index-finger. The fourth child was a baby girl, who had a very superficial parchment-like chancre of the tip of the tongue. In these cases I convinced myself that the mother was infected by the midwife, the father received the infection from his wife, who, by kissing, infected the first, second, and fourth children, while the third child, the boy, infected himself by picking with his finger the chancre on the cheek of his eldest sister. It has never been my duty to present so pitiable a spectacle to a medical class as that offered by that afflicted family. At the time of observation, Bardinet's[1] cases in Brive, France, were fresh in my mind, and I suspected the midwife to be the cause of infection. After much trouble I found this woman, in the person of an obese and elderly German, who had on the last phalanx of right index-finger a purplish fibroid cicatrix of the size of a silver three-cent piece, and undoubted evidences of a declining miliary papular syphilide. From facts which I gathered I was led to believe that this woman had carried the infection into two other families by contaminating the wives in childbed. These infected midwives being ignorant, know nothing o syphilis or the dangers of its transmission by means o finger-infection. Physicians, however, should clearly understand the *modus operandi* of this form of professiona infection, in order that they may avert it or ameliorate its sad consequences.

THE TREATMENT OF PULMONARY TUBERCULOSIS BY KOCH'S METHOD.

By C. E. QUIMBY, M.D.,

NEW YORK.

WERE the present paper simply the outcome of a ten days' sojourn in Berlin, I should hardly presume to offer it for general consideration. But I have desired for

[1] In this connection the following case is very interesting: Bardinet (Syphilis communiquée par le Doigt d'une Sage-femme. Annales d'Hygiène pub. et Méd. légale. July, 1874) was appointed by the local authorities to investigate the causes and nature of an epidemic which appeared in the town of Brive, France. He ascertained that those affected were parturient women (or their relatives, such as husbands and children) who had been attended at childbirth by a certain midwife. Upon investigation and examination of her it was found that in February, 1873, she had an ulcer on the border of the nail of the right middle finger, which was afterward followed by syphilitic manifestations. The syphilitic chancre upon the finger was very obstinate to treatment, and continued in an ulcerated condition until the following October. In the meantime she had attended, according to her statement, fully fifty women in confinement. It was only determined that fourteen women were infected by her with syphilis, though it was suspected that others were likewise contaminated, and that they concealed the matter from motives of shame and secrecy. The following are the facts: Between February 28th and March 15th she cared for three women who became syphilitic. Between the latter date and June 28th, though she attended a number of women, no cases of syphilis could be ascertained to have occurred. From this date until October she attended fifteen more women, of whom only one escaped syphilis. It is suspected that in the interval of six weeks during which no cases of infection are noted, such did really occur, but that they were hushed up; again, it was thought that perhaps, during this period, or a part of it, the digital ulcer did not yield an infecting secretion owing to the applications which were then made. Eight of the husbands of the fourteen women who thus became syphilitic were also infected, as well as nine infants of the latter, four of whom died of syphilis. Thus we certainly have a total of thirty one cases of syphilis, out of which there were four deaths, caused by one woman who had a chancre on her finger. It is thought, however, that the actual number was nearly one hundred. The fact of the infection having originated from the woman's finger was very clearly established, but in the cases of several of the children it must be confessed that the syphilis underwent a rather early evolution.

The conduct of this midwife cannot be commented upon too severely, for she evidently knew of the serious nature of the disease which she was communicating, yet her cupidity incited her to continue her ministrations. She was tried, found guilty, and sentenced to a mild fine and two years' imprisonment.

In the discussion of Neisser's paper before mentioned, Fritsch stated that he had known eight midwifery assistants (young medical men) who suffered from digital chancres, and that he knew of one woman who was infected with syphilis by one of them.

As an historical fact it may be of interest to mention that in 1727 an epidemic of syphilis broke out in the little village of Sainte Euphémie, in the department of Drôme, France. This epidemic has been chronicled in history by Jean Bayer under the title "Mal de Sainte Euphémie." This scourge, it is stated, had its origin in a pustule upon the right index-finger of a midwife. During four months this lesion, accompanied with painful swelling of the arm and a generalized rash, existed, and all the time the woman exercised her calling. More than fifty women, her immediate victims, were infected upon the genitals, and from them the disease spread to their husbands and children. Though the course of the syphilis in all the cases was very severe, there is no mention of a fatal result.

Brumbilla (Caso importante de infectione sifilitica. Gazetta Medica Italiana, Lombardia, No. 24, 1877, page 231) reports the case of a midwife who became infected upon the left thumb, and had very severe generalized syphilitic symptoms and manifestations. She was treated and promptly cured, and there is no evidence that she, on her part, communicated the disease to anyone else.

This observation is rendered the more interesting by the fact that confrontation was accomplished, and the person from whom the midwife received the infection was found to have four ulcerated papules of the vulva and anus, and bi-inguinal adenopathy.

some time to call attention to a few general principles in the treatment of chronic disease which appear to have been very largely forgotten or neglected in pulmonary therapeutics. The one absorbing question of the day seems to afford an opportunity for a specific illustration.

The medical profession stands to-day where it has often stood before, ready to make new battle with an old and ever-victorious enemy. It seizes the freshly forged sword, and throwing aside all other weapons, nor heeding the warning of its Vulcan, rushes to the fray with all the eagerness of youth, but less of that moderation which becomes experience and should belong even to defeated adolescence. If one may prognosticate for enthusiastic America from so-called conservative Germany, there are still other and more humiliating defeats in store for the future.

No one who has studied this treatment in the hospitals of Berlin can deny that some outlined plan of treatment other than can be gathered from the reports of cases is highly desirable before this remedy reaches the general practitioner. I disclaim at the outset any desire to theorize. My purpose is simply to arrange in a plan of treatment the logical deductions from the pathology of pulmonary tuberculosis and Dr. Koch's own assertions as to the action of this remedy, and to point out that inoculations alone, without adjuvant measures, can never determine the full value of this substance. The farmer who owns a pair of horses does not leave his load of golden grain to rot in the field because each horse, when harnessed alone, has failed to move it. Experimental tests are justified, even in hospital practice, only when we have no data from which to deduce rules of practice. In general practice we are never justified in using a drug until we have such deductions. As a basis of argument in the present case, then, I desire to propose the following as therapeutic axioms:

I. In the treatment of chronic disease every measure which can produce or assist in the production of a desirable result, however small, must always be employed, unless antagonistic to a greater good.

II. Every remedy employed should be used upon the basis of its physiological action, so far as known, as applied to the pathology of the disease, with a definite purpose to accomplish definite results, and these results should be the measure of its dose and continuance.

III. Failure to obtain evident results in a given case, from a given remedy which is known to be valuable, does not justify its discontinuance unless it is working evident harm.

For completeness, let me state briefly the problem which demands solution, and the methods by which it may be solved. Without claiming mathematical exactness, the pathology of tuberculosis may be stated to consist in the fixation, at any given point in or on the tissues, of the tubercle bacillus, with subsequent hyperplasia of the fixed cells and coincident cellular infiltration. The anatomical result is a non-vascular mass of living protoplasmic elements surrounding tubercle bacilli. Such a tuberculosis may remain indefinitely as that alone, or may be followed by either a productive or destructive inflammation, with necrosis of tubercular elements, to which we give the name phthisis, and in which the part played by the bacillus is stated by the best authorities to be that of an exciter of necrosis. In this process the essence of evil in the action of the bacillus appears to be that it excites a poison necrosis of such low grade as to attack only the immediately adjacent non-vascular elements of low resisting power, without exciting a reactionary change among vascular and more highly resisting tissues. When this irritation is stronger, or the tissues more active, fibroid changes encapsulate the offending mass, unless a general inflammatory necrosis produces sloughing. So long, then, as the conditions at any given point are those of tuberculosis and not phthisis, any element which is capable of destroying the bacilli must either destroy the tubercular tissue or be absorbed by its cellular elements, and thus brought in contact with the bacilli. Nor is the condition essentially different when the smaller centres of tubercular change have become aggregated into larger masses, or are extending into previously unaffected tissues. With conditions thus fixed, with physiological laws established, and the necessity for constant activity in the pulmonary function as an essential to life, what are the possibilities for any remedy that could be made to order and guaranteed to accomplish the requirements? It may be stated as a mathematical deduction, that no remedy can be devised which will do more than one or more of five things:

1. Destroy the tubercle bacilli.
2. Develop inflammatory, degenerative, or necrotic processes in or about the tubercle tissue.
3. Induce necrosis of the entire tuberculous mass, with sloughing and consequent mechanical removal of the disease germs as well as involved tissue.
4. Produce absorption of previously softened, degenerated, or necrotic tubercular tissue.
5. Excite fibroid processes about or in the tubercular tissue, which shall either encapsulate it or cause its transformation into fibroid tissue, with practical arrest of bacillary activity.

It is evident that these lines of possible activity of a supposed remedy are not only of two opposed classes, but that one at least (the third) is of such a nature that no conservative therapeutist would dare attempt its accomplishment. To produce a distinct slough of any considerable portion of lung-tissue must be attended with such grave danger to the patient that we may, without weakening our argument, discard this proposition entirely. In determining the relations of a given substance to this action, we have, therefore, to consider only how we must employ it to avoid rather than attain this end. For the sake of completeness, we must also recognize two modes of action of a remedy under the first heading. Bacilli may be destroyed by the direct action of a substance upon the bacillus itself, or through nutritive, chemical, or other hidden changes in the tissues, which render them unfit soil for the development of a given bacillus. This latter contingency may also be discarded at present, since our knowledge of any such changes that can be ascribed to the remedy to be brought in question is absolutely nil. I must say, however, in passing, that just at this point appears to be a wide field for experimental investigation, where one may hope for large returns, though he sees but a short distance ahead.

Upon further analysis it is also evident that, while the two classes of activity are diametrically opposed in their pathological changes, the first three being destructive while the remainder are constructive, yet a combination of one or more from each class is essential for a complete relief of the disease. It is true, to be sure, that destruction of bacilli is technically a cure of tuberculosis; but as foreign tissue does not remain quiescent in the system, either absorption or fibrous conversion is practically a part of the curative process. Now, since judging from our knowledge of the action of drugs already in hand, we can hardly expect that any one substance introduced into the system will produce both destructive and constructive changes, except in so far as nature institutes the latter when the former are ended, it is evident that a single remedy is going to suffice for the cure of tuberculosis only when fully supplemented by nature's recuperative powers, or when the primary changes which it incites are fibrous in character, and so mechanically destructive to tubercle. It is also a second Q. E. D., rather than even a corollary, that when any remedy is used whose activity falls in the first class, it should be supplemented if possible by one of the second class, and always followed by every known measure which can stimulate the system to the highest activity in its natural efforts at repair. We turn now to the therapeutics.

Setting aside that small portion of our therapeutics which is purely empyrical, where a happy chance has

given us our drug, it may be broadly stated that all our medication falls under two heads, specific or adjuvant.

From the nature of the case the fo mer can be employed only where either pathological investigation has demonstrated a specific poison, or where logical deductions and clinical comparison show with almost equal certainty that such a cause exists, although it has eluded even the liliputian eye of an oil-immersion lens. Such medication is essentially exact, definite and pretermitting individual idiosyn rasy, unvarying. If syphilis and malaria were the only diseases we were called upon to treat, we might almost have our stock prescriptions dispensed in the slot machine.

And let me say as in a measure explaining the present excitement, that this is the belief which the average layman holds, that for every disease there exists a specific, either known or which will some day be found. and that the medical world passes from the ignorance of to-day to the wisdom of to morrow at a bound, not by patient climbing step by step. We laugh when it assumes the form of a horse-chestnut for the cure of rheumatism. We see it less clearly in the flood of patent medicines, while we are most provokingly blind to the fact that from a similar hope, if not belief, we quickly weary in the use of those measures which require effort on our part rather than the patient's. We smilingly order cod-liver oil three times a day for a year, but we speedily doubt the value of measures which *we* must repeat daily for three months. Yet both our failures and successes in the treatment of phthisis enforce the truth that it is by patience, and not pills, that we shall attain success. From the etiological standpoint alone, a specific medication may be predicated as possible in every specific disease, but etiology is not the only factor in the present problem, and pathological processes in this disease erect such a barrier of living elements between the entrenched bacilli and every attack ing poison, as heretofore to render the latter utterly inert. That the new remedy is no exception to this rule was known from the first, and Professor Koch's statement, that "it does not destroy the bacillus," at once put an end to all consideration of the treatment as in any such sense specific. It is thus put in the class of adjuvants, or those remedies which assist nature, which promote but do not change the natural processes of repair.

With lines of action thus mapped out, we have to consider in which one the lymph of Professor Koch must be applied. In accepting the remedy we must also accept, for the present at least, his affirmations as to its properties These he states as follows: "The remedy does *not* kill the bacillus, but the tuberculous tissue." If to this we may add the results of recent histological examinations as given from Virchow's laboratory, the actions of the remedy may thus be stated. It excites:

I. Degenerative and necrotic changes in living tuberculous tissue.

II. Inflammatory changes in the adjacent tissues which also tend to be destructive in character.

With these two changes accomplished, even to the development of an area of necrosis about the tuberculous mass, absorption becomes certainly a possibility, and for the time being at least the necrotic action of the bacillus is arrested. Moreover, and most important of all, the condition is changed from a conflict between active bacilli and non-vascular elements, to simple inflammatory necrosis in vascular tissues.

That such absorption of tuberculous tissue does take place, cannot be stated with authority; yet it is not an unfair or strained inference from Professor Koch's statement that, "in parts a disappearance or, as it were, a melting of the tissues seems to occur."

A comparison, now, of these affirmed actions of the remedy with the possible methods of cure in pulmonary tuberculosis, can simply serve to intensify our admiration for the comprehensive statements of Professor Koch as to the therapeutic value of this substance. While it may be admitted as possible, it is certainly distinctly improbable, that we shall be able to use a remedy, whose special power is in the production of tissue necrosis, in such minutely graduated doses as to develop a productive fibroid change in the affected parts. Since destruction of bacilli is also excluded by Professor Koch's own statement, there remains only necrosis with sloughing, or necrosis with absorption, as ends to which we should direct our efforts We have to consider, then, how we may avoid the first and accomplish the second, or excite an absorbable amount of necrosis. This implies, first, an estimation in each case, based upon the history, general condition of the patient, etc., of the grade and amount of inflammatory and necrotic changes which that particular patient will probably endure without breaking down of pulmonary tissue. I am aware that this is largely a matter of judgment, yet one who sees much of phthisis soon learns to recognize those signs of low resisting power which warn us that softening and excavation will follow close upon consolidation, or the equally certain indications that nature's forces are to make "a long pull and a strong pull and a pull all together" in the struggle for life. One would certainly never think of starting up necrotic processes in the lungs of the former case to the same degree as in the latter. Upon this consideration alone both the quantity and frequency of the inoculations will be as varied as the patients. It is also at this point that experience and judgment—what is called the personal equation—become most prominent. It implies, second, the recognition of those symptoms which indicate the extent and intensity of the local changes. They are principally the febrile reaction and the physical signs. One who has watched the cases in the Berlin hospitals must have more acumen than I possess to see that the doses are graded by any other consideration than the amount of febrile reaction. The same observer, however, cannot have failed to recognize that there is absolutely no fixed ratio between the febrile reaction and the pulmonary changes, as regards either their intensity or character. Anyone who has seen, as anyone may have seen in Berlin, a graded set of injections attended by the usual amount of febrile reaction, carry in one patient, during the space of two weeks, a condition of slight infiltration at the left apex, through extensive consolidation of the upper lobe, into a large cavity, with evidences of rapid softening in the adjacent tissue; while a similar set of injections, followed by essentially the same febrile reaction, were productive in a patient with more extensive primary tubercular disease, of only increased bronchial râles and some pleuritic exudation, can hardly object to the dogmatic statement that in pulmonary disease the physical signs, and not the temperature, following an inoculation should be our guides in determining both the amount and frequency of the injections.

I would not be understood, however, as regarding the fever curve as of no value. Although estimating it of secondary importance, I consider it a valuable danger-signal, and especially that portion which lies below the normal line, and which appears quite as properly to lay claim to the term reaction-curve as does that above.

There still remains the question whether the local necrotic processes were best kept continuously active, or after a brisk excitation allowed to subside for a time. The answer must depend largely upon the individual case. While I am personally inclined to the latter course, sufficient may be said upon either side to justify a clinical test, and it therefore falls outside imperative rules of treatment. Thus far we have considered only the destructive action of this remedy, and its power to produce inflammatory changes.

Were one to judge from the reports of cases and what he sees in foreign hospitals, he must conclude that this is the sum-total of the treatment. So far as I am aware, no one has gone beyond this in phthisis.

The destructive part of the treatment has been followed to the letter, while absorption and repair, upon which Professor Koch lays such stress, have been most confidingly entrusted to Providence. As a result, both

the laity and the elect are beginning to cry "*cui bono?*" It is at just this point that I desire to enter a protest. Such testing of this remedy tends quite as much to conceal as to prove its true value. And I do not hesitate to say that results obtained by its use among hospital patients, where not only all the surroundings are such as are known to favor the progress of the disease, but where only half, and that the dangerous half of the treatment as formulated by Professor Koch, can be carried out, can be accepted only in so far as they are favorable, and that even a rapidly-increasing death-rate among such patients cannot be taken as any indication of what results might be attained under favorable surroundings, where the remedy is used in conjunction with other measures which promote reparative processes. Necrosis alone is the road to death. Recovery can be reached only through absorption or fibroid change.

In his original article Professor Koch says: "If the therapeutic activity of the remedy is to be rendered as fruitful as possible, the peculiarity in its mode of action must be carefully observed. In the first instance, the living tuberculous tissue must be caused to undergo necrosis, and then *everything must be done to remove the dead tissue as soon as possible.*" To which I think one may justly add, and to prevent sepsis and destroy those bacilli which have been brought within reach of antiseptics. That we have resources at our command which assist in all these ways no one can doubt We are constantly seeing tubercular infiltration "clear up" by some other process than that of softening, nor have we ceased to use both internal and local antiseptics in phthisis because they are no longer "sure cures."

Shall we now lose our load of grain because the new horse alone cannot bring it? What we desire to know of this new remedy is not so much what it can do alone, as its power in combination; its value as an adjuvant to measures we already possess, and know to be good. Upon this basis I have outlined the following plan of treatment, which I am now testing with patients under favorable conditions.

Indications.—I. To prepare the patient's lungs for the inoculations by expansion, stimulation of circulation, and removal of mucous and catarrhal products. With some of the patients now under my care this had already been done by the use of the pneumatic cabinet; others are still undergoing this preparatory treatment.

II. To establish specific processes in the tubercular tissue by injections of 0.001,0.002, or more c.c. of lymph every twenty-four hours or oftener, until the physical signs indicate active changes in the lung.

III. To favor absorptive processes until the physical signs show a subsidence of the active changes.

For this purpose I do and shall employ the pneumatic cabinet. As this is not the place to discuss the physics or therapeutics of this instrument, a subject I shall consider later, I will only say that for the past five years it has done more in my hands for the relief of pulmonary tuberculosis than any other remedy; and state, what I think I can demonstrate to anyone who will afford me the opportunity, that it acts most powerfully to excite and promote the absorption of the products of consolidation and pleuritic exudation in tubercular disease of the lung.

Every measure which hastens the pulmonary circulation and expands the alveoli, tends to the same result, even if less powerfully.

IV. To saturate the blood with such antiseptics as experience has led us to use heretofore in phthisis, in the hope that with the necrotic changes and inflammatory processes their efficacy may be increased.

For this purpose I am at present using creasote in increasing doses, both by hypodermic injection and through the stomach. Other substances may perhaps prove equally or more valuable.

V. To render antiseptic so far as possible the free secretions and exudative and necrotic products, in the pulmonary lumen.

The choice of substances is less limited for this purpose. I have used peroxide of hydrogen, pure oxygen, and various antiseptics.

VI. To stimulate by every known means general nutrition.

I have not forgotten nor do I desire to ignore the fact so readily recognized, even before it was pointed out by Virchow, that in the absorption of this necrosed mass by the tissues, the bacilli must also be disposed of. But in considering, as I have done, simply the logical method of testing this remedy, the results of treatment can find no place. I cannot refrain, however, from recalling the physiological fact that absorption is preced d by liquefaction following infiltration by active, living, white cells, which may render the bacilli inert before they enter the lymph-vessels. It is certain that the system has means and methods of dealing with bacilli, as evidenced by the natural history of every specific disease.

It only remains to determine to what class of cases of pulmonary tuberculosis the above treatment is applicable.

Cases of phthisis may be divided with sufficient exactness into three classes:

1. Cases of pulmonary infiltration, with or without pleuritic changes, which have not reached the stage of softening. 2. Cases in which more or less rapid necrotic changes are going on. 3. Those in whom reparative processes are fairly developed.

It is, of course, to the first class that this treatment is particularly applicable, and it is perhaps safe to say that it may be tested in all such cases. We shall undoubtedly find, however, that it must be used with much greater care in such as have developed consolidation rapidly than in the more chronic conditions. I am inclined to believe that the resisting power which the system manifests to the invasion of the bacillus, will largely indicate its tolerance of the changes induced by the remedy.

In the second class of cases, where extensive and rapid necrosis has followed acute infiltration, any use of the lymph appears to me entirely unjustifiable before other measures have arrested, in a measure at least, the destructive changes. When these processes are chronic and moderate in amount, and the patient is suffering quite as much from general sepsis and exhaustion, moderate doses at long intervals may excite a healthier activity in the affected tissues. In the third class I am unable to see any object to be gained by the re-establishment of degenerative processes, so long as the patient's general condition as well as physical signs indicate an upward rather than a retrograde course.

Yet, when all has been said from a scientific standpoint, we shall often find ourselves moved by pity and sentiment, to make one final, even though despairing, effort to snatch some loved life from out the gathering mists of death. The cautious physician, however, can never forget that in this innocent-looking fluid he wields the weapons of nature herself, or fail to realize that the vast throng who faint and die under the baleful breath of the bacillus have never had a greater danger threatening them, or a stronger hand of succor stretched out for their relief.

44 West Thirty-sixth Street.

A Pathological Language.—A London physician has a patient who has a defect in his speech of a most singular character. The patient, a lad aged ten, and English by birth, is unable to speak his native language, but articulates a jargon which cannot be understood. He was examined by many doctors, none of whom could decide whether he spoke the same thing twice in the same way or not. The assistance of the phonograph was called in, and the lad, in the presence of several gentlemen, was asked to speak the Lord's Prayer and the alphabet. When a comparison was instituted between the various cylinders containing the record, it was found that there was no variation in the spoken words, and that it was quite possible for the language which the boy speaks to be understood by simply learning the various sounds.

KOCH'S FIVE ORIGINAL CASES.

By J. WARREN ACHORN, M.D.,

NEW YORK.

In Berlin, in the private hospital of Dr. Levy, on Prenslauer Strasse. Professor Koch worked out to its present state of perfection the solution of his lymph problem. The room occupied by him for this purpose is a small one at the extreme left of the hospital suite, the window of which looks into an inner court. A chair, table, table-topped cupboard with a row of shelves above it, small iron sink, and iron stove, something like an ordinary cooking stove; on the table a Zeiss microscope with any number of sputum mounted slides, dated, and lying about it; on the shelves rows of unlabelled bottles of various sizes, containing liquids of varying colors, in which the lymph was probably stored, unmixed; on the table-topped cupboard trays, stands, and funnels for filtering purposes, with the red-stained filter-papers still in them; the stove and sink with their deck-load of utensils, and you have the room complete as it was in September, with Professor Koch gone out of it only an hour before. In the next nearest room, much larger, carpeted, and furnished with a sofa, table, chairs, bookcases, etc., evidently a room for doctors to gather, Professor Koch made his first announcements, in confidence, to his colleagues, Drs. Levy, Pfiffer, and others, five in all, respecting his discovery, the virtues of his lymph, and how to use it. His first words were, as reported, "Ich habe es gefunden." The next room in order, the third, is where, upon September 22d, treatment with the lymph was begun, the patients being five men, four of whom were suffering from phthisis, and the fifth from suppurating tubercular glands of the neck, that had been operated upon surgically. Their ages were thirty-eight, thirty-four, thirty-two, thirty-two, and twenty-two years. The cases of phthisis were apparently all chronic.

Just prior to November 13th, the date of the appearance of Professor Koch's article in the *Medicinische Deutsche Wochenschrift*, announcing his discovery, two of the four phthisis patients were discharged as cured, no bacilli appearing in the sputum expectorated by them. In these cases the lymph had been injected according to the reaction, and repeated as soon as the conditions were again normal, one or two milligrammes of a one per cent. solution being used each time. As soon, however, as reactions ceased to follow the injections, they were made only once in six to twelve days, and this would seem to indicate that the lymph was expected to have its effect irrespective of any marked symptoms.

On November 21st the two remaining cases of phthisis showed fewer bacilli in the sputum expectorated, and there was freedom from night sweats and fever. During the first three weeks' treatment one milligramme daily was given these patients, but subsequent to that time the injections were made only once in twelve days. In all four of these cases the sputum became tenacious, thinner, and whiter. Case No. V. of the original was especially interesting, the incision in the neck refusing to heal under any known treatment, injections of iodoform among other remedies being tried. November 25th, this patient was sitting up, had gained one pound in weight while in bed, and there were healthy granulations appearing in the wound in the neck. Patient had had no injection of lymph in fourteen days.

November 12th, a case of tubercular conjunctivitis was admitted, in a girl aged twenty. On November 24th she was given three milligrammes of a one per cent. solution of lymph experimentally, she having previously had four injections in all of the strength of one milligramme each. Her temperature went up to 40° C., when she developed acute laryngitis, which lasted as long as the high fever, with 80 respirations to the minute and pulse at 156. Eighteen hours after this injection the girl was in a heavy stupor.

November 23d, a case of tubercular cervical glands was admitted in a girl fourteen years of age. Given ten milligrammes of a one per cent. solution, experimentally. Her temperature rose to 40.8 C.; pulse, 140; she vomited, had chills, and became stupid, her breathing being stertorous and heavy. In twenty-four hours her temperature was again normal, but twelve hours later there was a return of the fever, the stupor, and the heavy breathing. There was great swelling about the neck, all the cervical glands under the jaw being involved. The swelling and induration interfered seriously with her breathing. Had the larynx and pharynx been equally affected the case might easily have resulted disastrously.

The smallness of the injections persisted in at Dr. Levy's clinic, under Professor Koch's immediate supervision, the fact that results were expected whether marked reaction followed the injections or not, coupled with the history of unexpected and startling phenomena following the giving of lymph in some cases where small amounts only were used, leads us to the conclusion that we are justified in using only small injections of so violent a poison.

AMPHITHEATRE OPERATIONS.

By OTIS K. NEWELL, M.D.,

SURGEON TO OUT-PATIENTS, AT THE MASSACHUSETTS GENERAL HOSPITAL, BOSTON, MASS.

Considering the great advance that has been made in surgery, from the time when "but to touch the peritoneum was considered fatal" to the day in which five hundred or more consecutively successful cases of laparotomy may be reported, we are undoubtedly confronted by the fact that underlying all this there must be a principle so true and incontrovertible that the laws which it establishes should be observed to the very letter. If we are willing to admit this we must also acknowledge that many further changes are needed in every system of antisepsis before it can be brought to a state approaching perfection.

Among these changes, I believe, there can well be placed the abandonment of the old style amphitheatre as a place in which to perform capital, if not all operations, upon sound uninfected tissues. The amphitheatre is essentially a place for spectacular demonstrations to large audiences, and as such is a most valuable means of discipline for the student who may there be placed "under fire" in the training which is necessary to accustom him to what in the early part of his career he finds so hard to bear. For demonstrations and lectures to large audiences, therefore, upon such cases as do not require the strictest antiseptic treatment, that is those which come to us already in a septic condition, the amphitheatre furnishes the best structure devised from the time of the great Roman arena to the day when such places were built to watch the progress of science rather than mortal combats. I believe that every operation among those indicated, even to the removal of a finger, would be done to best advantage in a small operating room where the possibilities of infection could be most carefully watched and most successfully eliminated. An infected and suppurating finger wound may extend from slight disability to the loss of hand, arm, and even life. How important is it, then, to the artisan at our clinic, who earns with the labor of his hands his daily sustenance, that we should eliminate as far as possible for him all exposure to infection. Changing in polyclinics from one case to another how hard we often find it with our best efforts to do this successfully in every case.

When we come to capital operations, however, there can be no question, I think, that they should be confined to the modern small operating room before limited audiences. The exposure of large surfaces to infection is perhaps more dangerous in open flesh wounds than in the peritoneal cavity, where we have more to fear from long temperature changes in many cases than anything else. We all know how splendidly the peritoneum is able to handle considerable amounts of infectious material, while under certain conditions a sudden temperature shock, such as a

piece of ice placed upon the intestines in animals, causes instant paralysis of the heart's action. Small operating rooms are therefore of further advantage in maintaining a high and even temperature without draughts—points of great importance in peritoneal operations. It may be said that so much precaution as this is not necessary, that we can depend upon final disinfection of the wound and field of operation. This may be true, and is no doubt in many cases, but, if we believe in the great principle, where ought we to make exception to it? How is it that in many cases where the best of care has apparently been taken, we find, to our consternation, a knee-joint, a peritoneal cavity, or a large resection wound bathed in pus and our patient's temperature remaining hopelessly high. Fortunately such occurrences are not common, but since they do happen, where shall we stop? At the disinfection of our wound, the washing of our hands, boiling our instruments, changing our clothes, or at what point? I believe at no point, until we reach that condition under which every possible and practicable means has been adopted for the avoidance of disaster from wound infection.

If, as might be said, "he who runs" may catch the measles, how can we know that the presence of a number of persons from a pathological examination or from some septic operation may not under certain conditions be a serious menace to the welfare of our case? Or how can we know that, with a mixed system of operating upon septic and aseptic cases, a sponge or other instrument used in a rectal case or for some foul pus-cavity may not, in spite of our best care, be employed with material for an aseptic operation? No matter how watchful we may be, or how vigilant our assistants, mistakes and unrecognized sources of infection seem bound to come, and that will be the most successful system which offers to them the fewest opportunities. The best operator to-day, from the strictly operative stand-point, is the one who is most successful with his antisepsis. Tissues may be torn out and yet will heal kindly, but though removed on the finest lines and with beautiful precision they will be ungrateful to the operator if by some chance his watchful eye has not been able to detect the unwitting carrier of infection.

It seems rather in line with this advance, if such it be, to believe that surgical clinics would be far more profitable to patient, student, and teacher if the old time visit *en masse* with touching elbows and craned necks were to give way to closely watched antiseptic drills in small squads.

Clinical Department.

OXYGEN AN ADJUVANT IN DEFECTIVE ARTERIALIZATION.

By F. M. JOHNSON, M.D.,

BOSTON, MASS.

The following case, of a class fortunately rare, illustrates the relief that may ensue from the use of oxygen when palliative treatment alone is possible.

On the morning of November 17th, was called to Mrs. T——, aged sixty-five, a woman of heavy build and weighing over two hundred pounds. There was no history of rheumatism, but I learned that she had previously suffered, at times, from severe precordial distress and disordered action of the heart. These attacks, however, were of short duration and had not occurred for some time, and she was thought to have entirely recovered.

Found the patient struggling for breath; respiration very rapid; pulse weak, 140, and slightly intermittent. Cyanosis of the lips and finger-nails was present in marked degree. She was in profuse perspiration, and on auscultation mucous râles were heard over both lungs.

Diagnosis of chronic myocarditis was made; the dyspnœa was caused by failure of compensation inducing ae pulmonary œdema and resulting six days later in hypostatic pneumonia. Diagnosis was sustained by consultation. At first the case was treated with morphine and atropia hypodermically; champagne, and concentrated fluid foods. Stimulating and nutritive enemas were used as occasion demanded.

This treatment produced very little relief, and, as soon as it could be procured, a cylinder of oxygen was placed by the bedside, and at short intervals the oxygen was allowed to escape, the tube being held as closely as possible to the patient's nostrils. Relief was immediately obtained and the severity of the symptoms very perceptibly lessened.

On the advent of pneumonia the oxygen was more freely used, producing a marked sense of comfort. Food was well retained. The patient, however, grew gradually weaker, although seemingly suffering but little, and death ensued on the eleventh day without a struggle. In such hopeless cases, where the ordinary remedies avail but little, the comfort derived from oxygen makes it worthy a trial.

The Tudor.

PAINLESS CIRCUMCISION.

By G. W. OVERALL, M.D.,

MEMPHIS, TENN.

For the past fifteen years I have performed circumcision quite frequently for the relief of various nervous disturbances. Since the introduction of cocaine I have used it almost exclusively in men, and frequently in children, by injecting it beneath the integument in the prepuce (having previously placed a rubber band around the penis half an inch or more back of the corona to limit its effect to the prepuce).

The pain attending the introduction of the needle into the sensitive skin has been a serious objection in men, and almost as bad in children as the operation itself. Then I have had various postponements, and often complete abandonment of it, because I could not promise "that it would not hurt." Now I can promise an operation where a child would not even know it until it was performed.

I do not want my patient to see the operation, and in the case of a child I conceal the instruments. I then place the patient upon his back and lay a small pillow on his chest so that he cannot see over it. I then adjust the rubber band, take a freshly prepared thirty per cent. solution of cocaine and inject with a small blunt-pointed syringe a few drops into the preputial orifice, at the same time I hold the end of the prepuce with my left hand, to prevent the escape of the fluid. I then press upon the fluid with my right hand to enable it to come in contact with the entire mucous membrane. I hold it for five or six minutes, when the mucous membrane is completely anæsthetized. I then introduce carefully my hypodermic needle through the preputial orifice and penetrate the mucous membrane and inject a few drops of cocaine. I then move it to another part and repeat the injection. It necessarily requires caution to prevent puncturing the integument, which would cause pain. I operated upon a child six years old, very small, nervous, and excitable, while he was discussing with his mother the kind of toys he would get for Christmas. I also operated upon a boy fourteen years old that came from an adjacent town (using silk-gut ligature), he did not feel the slightest prick of the needle. He returned home the same evening and recovered without a bad symptom. It is always better to use a ligature that does not require to be removed.

LIGATURE OF THE CAROTID ARTERY FOR ANEURISM OF THE OPHTHALMIC.

By W. W. BAILEY, M.D.,

FORT SMITH, ARK.

On September 19th Dr. J. W. Pruitt, of Russelville, Ark., brought to Dr. George W. Smith, for treatment, Gertrude V——, a girl aged thirteen, who four years ago

was accidentally struck with an umbrella rib in and above the inner canthus of the right eye. This produced a large extravasation of blood in the cellular tissue around the globe, and was soon followed by a pulsating tumor in the orbital cavity, which increased in size, with bruit and thrill distinctly felt and heard. Dr. Smith's examination showed that the external veins of the globe were enlarged, with a great deal of conjunctival congestion and a varicoid condition of the superficial blood-vessels of that side of the face, producing a decided deformity. The right optic nerve had the appearance of receding neuritis. The retinal vessels were obscured at various points. V. = right eye, some of $\frac{1}{20}$; that of left eye, $\frac{1}{10}$. Drs. Smith, Pruitt, Stephenson, and myself diagnosed the case aneurism of the ophthalmic artery. The tumor was rapidly increasing in size, extending above the supra-orbital ridge, and it was decided to tie the common carotid artery of the same side for relief.

Accordingly on September 21st the patient was anæsthetized and, with the valuable assistance of the physicians named, I performed the operation. From the first the anæsthetic produced distressing nausea, which lengthened the operation; otherwise nothing happened to interfere. The nerves, artery, and vein were in normal position, and the artery was safely reached and secured. The ligature used was an antiseptic heavy black braided silk, the superficial sutures were of fine silk with intermediate fine gut. On the 30th the stitches were all removed, the wound had healed by first intention, and the ligature only remained, the distal end protruding from the lower part of the incision. Distressing nausea continued day and night until the morning of the 23d, when it ceased. From that time until the twelfth day afterward she had a restricted diet of peptonized milk and infant's food. After this she was allowed a more generous diet. October 18th she was permitted to go home. The aneurismal tumor was then greatly diminished in size with a thrill only faintly felt at the inner canthus. The ligature was still firm and in position, but it came away on the 30th. Since that time Dr. Pruitt, her physician, writes that the operation has benefited the patient seventy-five per cent.

APOMORPHINE AS AN ANTIDOTE FOR POISONING BY STRYCHNINE.—ESSENTIAL HYDROPS.

By W. J. RANSOM, M.D.,

LOCKPORT, N. Y.

I NOTICED in a recent issue of the MEDICAL RECORD two articles which were of more than ordinary interest to me from the fact that I have had cases in my own practice similar to those therein described. I was once called to see a man who had taken by mistake an overdose of fluid extract of nux vomica. He had taken the liquid from the bottle without measuring it, and did not know the exact amount. He immediately took an emetic dose of ipecac, and telephoned for me. I saw him about fifteen minutes after he had taken it and the emetic had not taken effect. I was prepared for the emergency and had chloroform, etc., with me and also apomorphine in the form of hypodermic tablets, one-twelfth of a grain each. I immediately gave him a tablet hypodermatically, but had no more than removed the needle when he had a terrible convulsion. I administered chloroform and in a short time the convulsion ceased. For a moment I feared that he was past help; his pulse was barely perceptible and the heart-sounds were feeble. In a few moments he rallied, vomited freely, and perspired profusely. He did not have another convulsion. I gave chloral and potassium bromide through the night, and the next day my patient was all right. At the time I thought that, aside from the emetic effect of the apomorphia, its general relaxing effect had combated the convulsive effect of the nux vomica.

In regard to the effect of anæmia, as shown by œdema, especially of the lower extremities, I have had experience in several cases, particularly among kitchen girls in restaurants. I have also had two cases of anæmic ascites—one a school-girl aged thirteen, the other a young boy ten years of age. In both cases the abdominal cavity was distended with fluid and the necessity of paracentesis seemed imminent. In none of the cases was there any kidney complication and in all anæmic murmurs were present. In one case there was a return of the œdema of the lower extremities in the course of a year, but it yielded to treatment. In most of the cases tincture of ferri chloridi in full doses (twenty drops twice a day largely diluted in water) and milk was the principal medication; in some cases pepsin and hydrochloric acid were prescribed, and in others, where the tincture was not well borne, I gave syrup of ferri iodidi; I also gave laxatives when constipation was present but did not give hydragogues. In the cases of ascites I used the syr. ferri iodidi and applied iodine tincture externally. Recovery took place without the necessity of tapping.

CASE OF TRAUMATIC TETANUS—RECOVERY.

By FREDERICK J. WOOD, M.D.,

BROOKLYN, N. Y.

JAMES Mc——, aged ten, was brought to me at the Dispensary by his mother, on September 15th, complaining of stiffness of the jaw. A finger could scarcely be pressed between the boy's teeth, the muscles of the neck were becoming rigid, and the pupils were contracted. I found a jagged wound (which had been made nine or ten days before by the boy's stepping on a piece of glass) on the plantar surface of the left foot, running from within outward and forward through the arch. It was foul and sloughing. The extensor and flexor muscles of the big toe were contracted, so that the second phalanx was extended, while the third phalanx was tightly flexed. Temperature, pulse, and respiration were normal. Ordered to bed, and gave fifteen grains of bromide of potassium and ten grains of chloral hydrate every two hours, and a poultice of flaxseed to be applied to the wound.

The next day called at the boy's home. He was very restless, trismus more marked, and muscles of legs and abdomen were stiffening. Temperature, respiration, and pulse normal. Wound washed off with solution of corrosive sublimate and fresh poultice applied. Milk punches were ordered. Had patient moved to a dark room, which there happened to be in the house, where patient was more easily accessible to me, and away from the rest of the family. Two days after there was complete opisthotonos, and patient bit his tongue several times. Ordered medicine to be given every hour. The next few days saw the opisthotonos disappear, but the muscles were still quite rigid. The wound looked healthier, but the poultices were continued until September 29th, when it had completely healed. It was very painful, however, on pressure after the healing, and a clonic spasm of the muscles of that leg was sometimes reduced by touching the cicatrix. As hallucinations became very pronounced, the bromide and chloral mixture was stopped, except at night on failure to sleep, and $\frac{1}{16}$ grain of morphia sulphate and $\frac{1}{150}$ grain atropine given every two or three hours.

In this way patient went along without an untoward symptom till October 6th, when the writer was hurriedly called to see him. He had slept for four hours; breathing was labored, lips were bloodless, and he could not be roused, the friends said. He awoke soon after my arrival, and was perspiring very profusely. Muscles of neck and abdomen were flaccid. Temperature in the axilla, 104$\frac{1}{5}$° F. Heart, rapid and feeble. Was very irritable and delirious. Injected $\frac{1}{10}$ grain digitaline, $\frac{1}{4}$ grain morphia sulphate, and $\frac{1}{150}$ grain atropine together, the needle causing a spasmodic contraction of all the muscles. In a few minutes there was an improvement of all the symptoms. Next day (October 7th), patient was

brighter. Temperature, 99⅘° F., pulse 120, but strong. On October 8th, ordered five-grains quinine t.i.d.; but patient was still very irritable, and on October 10th refused to take either food or medicine. Temperature, 99° F. Pulse rapid and feeble, 130. The exhibition of a tube, and threat to feed him through the nose, had its moral effect, and he began to take his milk, whiskey, eggs, and quinine as before, and from that time he gradually improved. Saw him last on the 6th of this month (December), when he walked into my office. He complains of soreness of the left foot, where the wound was, and has a slight limp.

It is not claimed that any special drug was instrumental in effecting a cure, but I consider that the dark room was by no means an unimportant part of the treatment.

AN APPARENT CURE OF ACUTE PULMONARY TUBERCULOSIS.

By N. McCABE, M.D.,

NORTH PLATTE, NEB.

THE following case would seem in accord with the opinion of Dr. McCall Anderson that acute phthisis is curable.

The patient, a female, aged twenty three, gives a family history distinctly tubercular, a brother and sister having recently died of tuberculosis, after a lingering illness of two years' duration, in both cases. She suffered from habitual cough, although not of a distressing nature, for several months, but presented, during this time, no further symptoms of an existing tuberculosis. General health good; no emaciation or loss of appetite; continued to perform her duties as a domestic servant without interruption until acute symptoms set in. Suddenly the cough became more severe, with considerable expectoration, general lassitude and fever increased in the afternoon. Appetite and strength began to fail, while perspiration was at times quite profuse. After about two weeks, during which time the patient was able to be up at intervals, she became profoundly prostrated and was obliged to remain in bed all the time.

At this time a sister of the patient presented herself in tears at my office, saying that her sister was dying of quick consumption, as the physician in attendance had pronounced it such, and had given up the case as hopeless. She requested me to call and do what I could for her in her last hours.

I found the patient much prostrated; pulse, 120; temperature, 104½° F.; respiration, 56 and much embarrassed; face pale and haggard and perspiration profuse. Physical examination revealed dulness, especially marked over the apices of the lungs, with fine râles distinctly heard anteriorly.

Ordered stimulants, with milk and beef-tea, to be given in small quantities frequently repeated, and antifebrin to reduce the temperature. The administration of antifebrin was followed by a most gratifying reduction of temperature, without any appreciable increase of prostration. About thirty grains were given in twenty four hours. A tablet containing morphine sulphate, ⅛ grain, and atropine sulphate, $\frac{1}{150}$ grain, was given each night to control the cough, which was very annoying.

The perspiration, which was almost continuous, although somewhat increased within an hour after the administration of each dose of antifebrin, had in the aggregate become less on the second day of the treatment, and continued to grow less throughout.

This line of treatment was continued for three weeks, when the fever had entirely disappeared, with appetite and strength slowly but steadily returning. Râles and dulness disappeared; respiratory murmur clear and distinct over both lungs.

Convalescence continued without interruption and the patient is now enjoying good health, the cough from which she suffered before the acute symptoms set in having disappeared.

The cure in such cases may be explained on the hypothesis that the patients already suffering from incipient tuberculosis are attacked with pneumonia, the consequent inflammation of the tissues surrounding the tubercle, like that caused by the Koch lymph, giving rise to suppuration of the same, followed by the healing process.

ESSENTIAL HYDROPS.

By MARCELL HARTWIG, M.D.,

BUFFALO, N. Y.

WITH the greatest of pleasure I embrace the opportunity to answer the first objector, so much more as there is some subsequent history to be added to this singular case. Readers who overlooked the previous communication I refer to the RECORD of September 27, 1890. Incidentally I shall introduce the description of a new trocar. Horace was right in advising an author to consider his work for nine years before its publication, but what shall we do in our electric times? Had I not published my first case of wiring the patella immediately after recovery of the patient I could not claim priority over Lister. Therefore I had to publish the case of essential (inflammatory) hydrops, although there is now a subsequent history to it.

The girl in question was feeling well and going about, although not working, from July 22d until September 20th, when I was called in attendance again. Fever had again set in, and soon I had reason to suspect pleural effusion or pneumonia. The remarkable fact of bronchial breathing in the region of dulness, with slight dislocation of the heart, was puzzling, but Pravaz's admirable instrument solved the question, and, as salicylate of soda produced no effect in the case, I tapped the right pleural cavity on October 5th with my trocar and drew off a large quantity of amber-colored fluid which congealed directly after the operation. Doctor Schroeter kindly examined the coagulum for tubercle bacilli but could not discover any. The fever vanished, the pleural cavity did not refill again, and on October 15th the girl was well.

I called on her to-day and found her in good health. The new trocar which I used on that occasion has served me often so well in tapping the pleura that I describe it. The cannula of a common trocar is cut across and the two sections are held together by a firm metal brace shaped like a [ ]. The space between these is filled with a piece of rubber tubing securely tied over both ends of the cannula. About two inches from the point the cannula has a lateral outlet, with rubber tubing for attaching a pump. After plunging the trocar into the pleura and withdrawing the stem, the rubber portion of the cannula is compressed by a spring clamp, whereby the possibility of air entering the pleura is excluded. To be sure of perfect action, a test with water before operating should not be omitted. The fingers of an assistant can be substituted for the clamp; but the clamp is preferable for its lightness. This is the very advantage which my instrument has in comparison with other trocars.

Now as to what Dr. Ross writes. I thank him for mentioning simple anæmia as a possibility, as this condition was not particularly considered in my former article. Though the doctor's case is to him "exactly similar," I cannot refrain from doubting the fact; but taking it for granted that Dr. Ross saw such an exact similarity, then he treated a case of essential hydrops and omitted the opportunity to describe it. Was my case one of simple anæmia? Anæmia a febrile disease? That is something new to me, when pernicious anæmia is excluded. Anæmia of itself cannot cause dropsical effusions, except in dependent parts, as in the feet or on the back in the lying posture. In my case the anæmia was by no means profound. The girl had never missed a menstrual period until she became sick, and menstruation has occurred several times since. Everybody who has read my case will know that a little iron could not have been sufficient to

cure it. In Dr. Ross's case time may have been the curative element. At all events such an "anæmia" deserves to be separated from all other anæmias, with a new name, and search to be made for its foundation. This may be ultimately found to be of germic (*sit venia verbo*) origin. The next case of essential hydrops should have its blood subjected to bacteriological investigation.

PLACENTA PRÆVIA CENTRALIS WITH TRANSVERSE PRESENTATION.

By CHARLES J. PROBEN, M.D.,

CHARITY HOSPITAL, BLACKWELL'S ISLAND, N. Y.

Mrs. K-- , aged thirty eight; has had six children, all confinements prior to the last one having been perfectly normal, without any complications. The case was in charge of Dr. W. W. Stewart, to whom I am indebted for the history prior to the date of confinement, which is the following:

On August 20th, at 3 A.M., there occurred a severe hemorrhage, which had soaked through the bedding and formed quite a pool on the floor. On examination the cervix had a velvety feel, with rigid os externum, admitting with difficulty the point of the index finger. The os internum was impervious. Ballottement indistinct and a marked pulsation could be felt with the point of the finger. The woman complained of "feeling life" to an unusual degree, and on palpation violent movements could be perceived. This hemorrhage was treated by borated cotton tampons, rest in bed, and 15 milligr. of sulphate of morphine. The patient slept well for seven hours, at the end of which time it was found that the hemorrhage had entirely ceased. Pulse, 110; temperature. 101° F. On vaginal examination the diagnosis of placenta prævia centralis was made. The induction of labor was advised, but was refused by the patient. The vagina was then well douched and tamponed. This treatment was discontinued at the end of four days, there having been no recurrence of hemorrhage. She was furnished with tampons, instructed how to use them, in case hemorrhage should occur, and to send immediately for the physician. On September 15th Dr. Stewart was summoned and found the patient complaining of incapacity to hold her urine, and a heavy feeling in the lumbar region. On examination the cervix was found sufficiently dilated to pass the finger through the os internum and feel the placenta. Next day I was called in consultation with Dr. Stewart and confirmed his diagnosis of placenta prævia centralis with transverse presentation, dorso-anterior position, with head on a level with the right iliac crest and an excess of liquor amnii. The patient then said that she had had labor pains for two days, which were gradually dying out, accompanied with a slight bloody discharge. After examination quite a severe hemorrhage started, which, however, soon stopped. Later on, during urination, large blood-clots were passed from the vagina. Considering the circumstances, having before tried to do cephalic version by external manipulation, but failing, it was decided to do podalic version. The patient was placed on a table, chloroform administered, and a vaginal douche of 1 to 6,000 bichloride given. Dr. Stewart introduced his hand into the vagina, dilated the cervix quickly with the fingers, and detached the placenta completely. An alarming hemorrhage immediately followed. I quickly introduced my hand, delivered the placenta first, rupturing the membranes, and performed podalic version by pulling down first one foot and then another, assisted by manipulations through the abdominal wall. The legs and body were delivered, and the next difficulty was the extension of both arms above the head, which was managed by sweeping them over the face and chest and so extracting the shoulders. The cord was twisted tightly around the child's neck. The next obstacle was the delivery of the head, the chin becoming fastened under the pubic arch. Manual pressure upon the fundus uteri, and traction applied below, with flexion and extension, were tried, but all in vain, until finally the forceps were applied. When born the child was in a condition of asphyxia. Various methods of resuscitation were tried, and were finally successful. The child was then wrapped in warm flannel and laid to one side.

Meanwhile a copious post partum hemorrhage occurred, which was controlled by kneading the uterus, the use of ice in the vagina, and the administration of ergot.

On examining the placenta the membranes were found not intact, and hence necessitated removal by introducing the hand into the uterus. The uterine cavity was then well douched with hot 1 to 6,000 bichloride solution, which controlled all hemorrhages. The parts were well washed, and the vulva pad was applied, to be renewed every three hours. Four grammes of fluid extract of ergot were given, with 15 milligr. of morphine sulphate and whiskey hypodermatically. The pulse was quite weak and rapid, 140 to a minute, but the above-described treatment brought it down to 110. Temperature. 101° F.

The after-treatment consisted in giving vaginal douches, 1 to 6,000, three times a day for ten days. Catheterization three times a day. Whiskey and milk as required. The bowels moved on the fourth day. The patient was discharged on the tenth day, the mother and child both being in good condition. This case is interesting in so far that the abnormal presentation, complicated by placenta prævia, was treated by version, with delivery of the placenta before delivery of the child. This was followed by retained membranes and post-partrum hemorrhage, which greatly endangered the life of the mother, but still a rapid convalescence took place.

McDOWELL'S METHOD OF CONTROLLING EPISTAXIS.

By H. D. WOOD, M.D.,

FAYETTEVILLE, ARK.

I have read with considerable interest the article from Dr. W. W. Parker on "A Simple Substitute for Bellocq's Cannula and all other Methods for Controlling Epistaxis." I see that his method has been published in several medical journals, quoted from the Medical Record, and as no one has suggested anything better I ask for space to give the plan that Professor John T. Hodgen, of St. Louis, taught twenty years ago. He called it Dr. John McDowell's method.

It is to introduce a condom into the nasal cavity and fill it with air or water.

For fear some one may have the same difficulty that I had on attempting this method—that is, have the bag fill on the outside of the nose and pull out what had been pushed into the nasal cavity—I will give the method that I have practised.

Cut off two or three inches of the open end of the condom, as may be thought necessary, and introduce a No. 5 or 6 soft rubber catheter, leaving the bag to project about half an inch beyond the end of the catheter, as it will shorten when distended. Hold the cut end of the bag evenly around the catheter and take a few turns with a sewing thread, and tie securely to prevent it from leaking, but not so tight as to obstruct the lumen of the catheter.

Now dip this simple instrument a few times in clean water, hold the bag between the thumb and finger of one hand and twist the catheter with the other until it is brought in contact with the end of the bag.

While holding the instrument in this way ask your patient to forcibly blow the nose so as to free it from all blood-clots. Now introduce the instrument into the bleeding nostril until it lies just within the cavity. Then give

the catheter a turn in the opposite direction and fill it with air or water and plug the end so the rubber bag will remain distended. The catheter can then be fastened to the head with a bandage, or a cord may be tied tightly around it near the nose and cut off.

It seems to me that this is the simplest and safest method of plugging the nasal cavity. And it is so easy to remove it, all you have to do is to let the air or water out, twist slightly and withdraw the bag. When properly done it is the most cleanly and least objectionable of any method that I have seen described.

It might be well in some cases to use two condoms in making this apparatus, slipping one bag into another, to prevent, after operations, sharp spiculæ of bone from cutting through and spoiling the bag.

If any physician fears his moral integrity might be called in question by carrying about with him Dr. Condom's invention, he can cut one inch or two from the open end of the long bag and have left all he needs to plug the nose with.

Progress of Medical Science.

Uric Acid in the Blood.—Sir A. Garrod showed some years ago that during an attack of gout the blood contained appreciable quantities of uric acid. Abeles and Saloman have corroborated these experiments. In the *Deutsche Medicinische Wochenschrift*, No 23, of this year, Professor von Jaksch, of Prague, whose valuable researches on the blood are well known, publishes an interesting paper on the occurrence of uric acid in the vital stream. He considers mainly two points. 1. Whether uric acid takes a prominent part in the "acid intoxication" described by himself, Peiper, and others. 2. Whether it is only in attacks of gout that uric acid occurs in the blood. The blood was tested by Salkowski's and Ludwig's method, which Jaksch considers to be very accurate. The total number of patients on whom observations were made was one hundred and five. In nine cases of perfect healthy individuals no trace of uric acid could be detected, neither were there any xanthin derivatives present. In nervous affections, such as tabes, multiple sclerosis, polyneuritis, and tumors of the brain, the results were also negative; on the other hand, in such cases the blood frequent contained compounds of xanthin, especially hypo-xanthin. Nine of the one hundred and five cases were patients suffering from enteric fever, but uric acid was never found in the blood; in one case, however, in which the temperature had fallen, small quantities were discovered. In a case of irregular intermittent fever the results were analogous; during the febrile attack no uric acid could be detected, but in the intervals it was present. Diseases of the liver, intestinal tract, and stomach only led to "uricacidæmia" (as Jaksch calls this condition) when there was profound anæmia. Uric acid was found in the blood in cases of heart disease in which there was much cyanosis. In affections of the lungs and pleura it was most frequently detected in emphysema, and when there was pleural exudation. It occurred constantly and in considerable quantities during the febrile stage of pneumonia (five cases). In acute rheumatism it was never found. Fair quantities were present in renal disease—the different forms of nephritis. amyloid degeneration, etc. Considerable amounts were also observed in cases of marked anæmia, both primary and secondary. With regard to the second question, therefore, Jaksch comes to the conclusion that uricacidæmia is not pathognomonic of gout; as to the first question, he concluded that uric acid is not often found in febrile "acid intoxication," but that it may be so. It is important to notice that all morbid processes leading to overloading of the blood with carbonic acid also produce this condition, and the greater the cyanosis the more uric acid is found. Therefore it would seem that we must ascribe the presence of uric acid to a disturbance of the interchange of gases in the lungs, such as occurs so largely in pneumonia. How are we to reconcile with this statement the occurrence of uric acid in the blood in nephritis and anæmia? To this question Jaksch answers that in both these diseases the red blood-corpuscles, whose duty it is to further oxidize uric acid, are deficient. He concludes by making the general statement that uricacidæmia is due to disorders of the red blood-corpuscles, the vehicles by which oxygen is carried. —*The Lancet.*

Treatment of Habitual Constipation.—Professor Nothnagel considers the three most important elements in the treatment of habitual constipation to be massage of the abdomen, electricity, and abundant exercise. Abdominal massage cannot be properly performed by the patient upon himself, the effort required causing contraction of the abdominal muscles, which prevents deep pressure and manipulation. An efficient substitute for a masseur is a metal ball, weighing from three to six pounds and covered with cloth to prevent chilling the skin. The patient should every morning roll this over the course of the large intestine for five or ten minutes, beginning in the right iliac region. Professor Nothnagel believes that in the end massage is invariably of service, but that we must not expect much benefit for weeks, and perhaps months. As cases of long duration react but slowly to almost all methods of treatment, we must (in order to guard against the results of fecal accumulation) have resort to laxative mineral waters, drugs, or enemata. Nothnagel believes it better, under these circumstances, to avoid drugs, and only to use an enema, either of pure water or one containing common salt, olive oil, or preferably, glycerine. Acid fruits should be freely taken, along with a nutritious and easily digested diet. Should a vegetable laxative be called for, notwithstanding these remedial measures, Nothnagel recommends a pill composed of podophyllin and the extracts of aloes, rhubarb, and taraxacum.—*Medical News.*

Severe Traumatic Sciatica Cured by the Removal of a Spiculum of Bone from the Edge of the Great Sacro-sciatic Foramen.—At a recent meeting of the Clinical Society of London, Mr. Bland Sutton communicated the details of this case. The patient was chief mate of a sailing vessel; soon after leaving St. Vincent the head of his left thigh-bone was dislocated by a "derrick-boom" falling upon him. An earnest but rough attempt was made by the crew, directed by the captain, to reduce the dislocation; but this failed. A few days later reduction was effected, under chloroform, at a hospital in the Canary Islands. After the accident the patient suffered great pain in the thigh and leg, in the course of the sciatic nerve and its subdivisions. This he endured for six months. When the patient came under Mr. Sutton's care an exploration of the great sacro-sciatic foramen was made by an incision through the buttock, the patient being placed in the position of a body when the gluteal region is being dissected. This position greatly facilitated the steps of the operation. A spiculum of bone, 15 mm. long, was found at the edge of the foramen, in such a position that its point was pressed into the nerve when the limb was extended. The spiculum was removed with bone forceps, the cut edges of the gluteus carefully sutured with gut, and the wound closed. The patient made a rapid recovery, lost all his pain, and in a few weeks resumed his occupation.

Cystitis in Diabetes.—Dr. R. Schmitz draws attention to the occasional presence of cystitis in diabetes. It takes its origin apparently from the saccharine urine within the bladder partly decomposing and passing into a state of fermentation. If the vesical condition is favorable, the fermentation can be kept up, and recovery, or even improvement, is scarcely to be hoped for as long as the glycosuria lasts. In the chronic form Schmitz distin-

guishes three degrees. The first is very mild, with no subjective symptoms; and the urine is somewhat turbid, faintly acid, with numerous mucus corpuscles, and a few pus cells. From this the second develops, when the urine is more turbid and has an unpleasant odor. Its reaction is weakly acid or neutral, and it contains many mucus and pus corpuscles, triple phosphates, and bacteria. Subjectively, there is increased frequency of micturition. The third form is a more advanced stage of this. All the contents mentioned above are in greater amount; gas is formed in the bladder and passed by the urethra; and the subjective symptoms are more urgent. In many of these cases, according to Schmitz, the patients come under observation first for vesical catarrh, and the primary disease is apt to be overlooked. The prognosis of the first and second stages is good, while the third is not so favorable. It depends whether we are able to cure the diabetes or reduce it to a minimum, and this forms the most important indication. The cystitis ought to be treated energetically by frequent washing out of the bladder with a solution of salicylate of sodium to prevent decomposition and fermentation, combined with the internal administration of the same substance. This treatment should be continued until the urine becomes clear. The acute form of cystitis occurs rarely in diabetes. Schmitz quotes the case of a previously healthy lady who was taken ill with a rigor, a temperature of 104° F., symptoms of acute cystitis, urgent desire to pass water, great pain on micturition, retention, and the appearance of dark scanty urine. No cause could be assigned. Ten days after, when she was improving slowly, she was seen by Schmitz, and then the urine contained mucus, pus, phosphates, and four per cent. of sugar. On a rigid anti-diabetic diet and salicylate of sodium the sugar disappeared, and with it all traces of the cystitis.—*Berliner klinische Wochenschrift.*

Effect of Certain Substances on the Red Corpuscles.—M. Mayet, of Lyons, read a paper at the recent meeting of the French Association for the Advancement of Science, in which he gave an account of the effects of various neutral salts and of chloral on the red corpuscles of the blood. Solutions of the strength of one or two per cent. of chloride of sodium. chloride of potassium, sulphate of soda, phosphate of soda, bicarbonate of soda, and sulphate of magnesia, all at first temporarily destroy the elasticity of the corpuscles, and then dissolve or disintegrate the stroma. Solutions of the strength of five per cent. or more diminish the size of the corpuscles and harden them. The chloride of sodium has the most preservative primary action, but is most destructive on prolonged contact. As is well known, it has been recommended for washing the blood (in a 0.6 per cent. solution), in certain cases of poisoning. Sulphate of soda has a great tendency to preserve the chemical properties of the corpuscles, but makes them much more rigid than does chloride of sodium. It is not suited for intravenous injections, but is very useful in the laboratory for washing the corpuscles before preparing hæmoglobin from them. For this purpose it is better than the three per cent. solution of chloride of sodium, which is commonly employed, but which has a considerable tendency to dissolve the corpuscles. Chloride of potassium has a great preservative action, but cannot be used for intravenous injections owing to its toxicity. Carbonate of soda in weak solutions is very preservative. Phosphate of soda in weak solutions renders the corpuscles rigid for a long time; it preserves their form well, and so is useful in diluting the blood for the purpose of counting the corpuscles. Sulphate of magnesia does not dissolve them, but changes their shape more than any of the other salts. Hydrate of chloral is very destructive to the corpuscles when it is in a concentrated solution, but not when it is of less strength than five per cent. Intravenous injections of the latter, which may be repeated several times daily, are very valuable in tetanus, in uræmic convulsions, to calm the violent spasmodic attacks in rabies, and in some painful diseases where hypodermic injections of morphia are inefficacious or badly borne. Of course the effects on the heart, respiration, and urine must be carefully watched.—*The Lancet.*

The Free Acid of the Gastric Juice during Digestion.—Dr. Von Jaksch finds that free hydrochloric acid is present in considerable quantity as early as a quarter of an hour after the ingestion of food. The quantity depends on the character of the food, and usually reaches its maximum in from one to three hours. This increase, however, is not a steady one, but shows intermissions after the first hour and a quarter, hour and a half, or even two hours. It is always most rapid on a meat diet, slower on milk diet, and slowest of all on a pure carbohydrate diet. The greatest quantity of acid found in any one case—0.1615 per cent.—was obtained on a milk diet—(fourteen observations), slightly less on a meat diet—0.1563 per cent.—(eleven observations), and least of all on a carbohydrate diet—0.1102 per cent.—(ten observations). Digestion appears to be completed most rapidly on a meat diet, next in order coming carbohydrate and milk diet. He concludes that entire absence of free hydrochloric acid from the gastric juice, or its presence in traces only, during the first quarter to half an hour of digestion, is without pathological significance. If no free acid is present one to three hours after ingestion of meat or milk, it is extremely probable that some severe disturbance of gastric function exists. On a carbohydrate diet, on the other hand, the presence of a mere trace of free hydrochloric acid is quite consistent with conditions of health. Furthermore, we are not justified in concluding that the presence of free acid in considerable quantity two to three hours after ingestion of meat or milk points to some pathological condition, as wide variations are possible within physiological limits.—*The British Medical Journal.*

Observations on Certain Forms of Intestinal Obstruction.—Dr. Jessett announces the following conclusions, based on a wide experience (*The Medical Press*): 1. Obstructions of the intestines the result of constricting bands of volvulus are always met with either in the small intestine or the sigmoid flexure. 2. The most common cause of bands is old peritonitis, local or general; Meckel's or other diverticula may be the cause of constriction of the bowel by snaring or twisting. 3. The predisposing causes of volvulus consist in elongation of certain segments of the intestine, abnormal length of the mesentery, adhesions, or unequal peristaltic action. 4. The higher in the intestine the obstruction the more severe usually are the symptoms. 5. All cases of obstruction should be treated by early abdominal section, and if possible reduction of the constricted portion of the intestine by dividing of constricting bands or untwisting a volvulus, that is if the gentle insufflation of hydrogen gas fails to effect reduction. 6. In all cases where the intestine is very distended, it should be freely incised and its contents evacuated. 7. In all cases in which the constriction is irreducible lateral anastomosis by approximation discs should be practised so as to exclude permanently the seat of obstruction from active fecal circulation. 8. In cases where gangrene has taken place in the loop of constricted intestine it should be excised, and the portion of intestine above and below the seat of constriction should be united by lateral anastomosis by approximative plates; the divided ends being invaginated into themselves. 9. All bands and diverticula should be removed, when practicable, at the time of the operation; in the case of volvulus, if the mesentery is abnormally long it should be shortened. 10. That enterostomy, or the formation of an artificial anus, should never be performed unless it is found to be absolutely impracticable to re-establish the continuity of the intestinal canal by dividing the constricting bands by enterorrhaphy or by means of lateral apposition as described.

MEDICAL RECORD:

New York, January 17, 1891.

THE LYMPH AND ITS REACTIONS.

THE publication of Professor Koch regarding the composition of the lymph, considering the great expectations which have been aroused concerning it, is rather disappointing than otherwise. With few exceptions his statements have been already anticipated, and in many other respects no new facts have been added to those that have been accumulating during the past few months.

Aside from the mention of the ingredients contained in the fluid we are in little if any better condition as to the possibility of its production in our own laboratories than we were before. Still, the information, as far as it is given, will add much interest to the study of the results of lymph treatment in their relations to the supposed causes of their production. In other words, we are so much the better enabled to think for ourselves, and so much the more encouraged to work in accumulating data by which the new theory must stand or fall. We are making enough progress in the latter direction to take courage accordingly, and hope for the best in the direction of eventually settling many of the mooted points of a startling revolutionary doctrine.

Much of the interest of our investigations has centred upon the value of the reactions, general and local, as diagnostic of tuberculosis in various parts of the body. Although the reactionary phenomena have been quite uniform they have proved to be far from absolutely so. In numerous exceptional cases patients with well-marked phthisical symptoms have failed to respond to the diagnostic test, while the contrary has been true with patients who have been suffering from other than tuberculous diseases, or who are, in the general acceptance of the term, perfectly healthy. It is in no spirit of adverse criticism that such conditions have been noted, but rather with a feeling of disappointment that earlier anticipations have not been more fully realized. We are being forced to the conclusion that the value of the local and general reactions are more relative than positive, and that many modifying circumstances must necessarily be taken into account.

Then as to the supposed mode of action of the lymph in destroying tuberculous tissue, or scattering the bacilli, there is opportunity for much difference in opinion. The doctrine of specific action is losing rather than gaining ground in the light of present clinical experience here and abroad. Fortunately, the autopsies have been few, and pathological opportunities have been limited. So far there have been few lesions peculiar and striking enough to show any direct relations of cause and effect in the use of the remedy. Many observers have noted no changes whatever in tuberculous joints opened by surgical operation after the lymph has done its reactionary work, while others have described degenerative changes which may or may not have existed before the inoculation treatment was commenced. The examinations of lung lesions have shown equally various conditions from that of limited areas of injection around decomposing tubercular masses, as usually seen in cases under ordinary treatment, to that of extensive infiltration of neighboring tissue. The latter phenomena have been described also in connection with tubercular diseases of the larynx, where suffocation has been thereby threatened, and particularly in cases of lupus, in which the turgidity of surrounding parts has been almost the rule, and has been associated with incrustation of the surface.

While such effects confirm the predictions of Professor Koch regarding local reactions, and encourage further study, we have as yet made no notable progress in ultimately curing tuberculosis, or in proving that the lymph acts differently from any other substance containing an active albuminoid substance capable of producing systemic poisoning with local manifestations. Theorizing on this basis, it would be legitimate to assume that any organic poison, similar to that which the lymph contains, would attack most strongly a weakened body, such as we find in tuberculous patients. The parts invaded by a degenerative disease, and necessarily most lacking in vitality, would be the first to be affected. As a consequence, strong reactions might easily occur in the shape of increased local congestions and infiltrations, with the usual attendant phenomena of an augmented general febrile disturbance. From such a stand-point it may not be difficult to understand how the tuberculous tissue as such might be killed independently of any elective action of the lymph.

At best, we must admit that the simple destruction of the diseased tissue, even if such can always be assured, is but a part of a very complex process of cure for tuberculous disease. Something more is required than mere injections and resulting reactions.

From what we now know of the cause of tuberculosis we can safely venture to say that no cure can be guaranteed until we can prove our ability to kill the bacilli in the human body. When this latter is possible there will be hope even for the most advanced cases. At best we can now get rid of the bacilli only in an indirect, and not always certain or complete, manner by burying them in decomposing tuberculous tissue and sloughing them away in the current of expectoration. When such cannot be done the bacilli remain in a more or less quiescent condition, awaiting their opportunities for further mischief.

While we may congratulate ourselves that we have even progressed thus far, we have scarcely taken more than a first step. Much more difficult tasks are the safe elimination of the rapid local decomposition occasioned by the lymph and the subsequent reparation of the invaded parts. Already we are told that in cases of tuberculous joints and glands relief can be obtained ultimately by surgical measures only.

So far our main hopes for permanent cure of lung

disease are based upon the well-known efforts of nature to rid herself of the decomposed products by expectoration, while the general strength of the patient is being maintained by the most powerful tonics and the most assimilable nutrients. While thus the lymph may aid us in one direction by hurrying the initiative processes, we are driven in the end to help ourselves by resorting to the ordinary but good old-fashioned methods. We have scarcely gone beyond this at the present stage of our inquiry, awaiting as we are the proofs that the new method of cure is quicker and surer than the old one.

What becomes of the bacilli which are not directly affected by the lymph treatment is a question of considerable importance. The statement of Virchow that when they are routed they are scattered in adjoining sound tissue is doubtless backed by a careful and intelligent study of post-mortem appearances. Although it would appear to be exceedingly difficult to prove that these migrations might not have occurred in the natural way, and independently of the action of the lymph, the contrary possibility might be reasonably entertained. Until, however, more definite facts than those already offered are given it will be well to suspend judgment.

RECIPROCITY IN MEDICAL PRACTICE.

The Swiss Government not long ago withdrew the permission to practise which it had previously granted to English physicians resident in different health resorts of the country, and declared that they had no right to treat the sick, whether their own countrymen or Swiss, without having been properly qualified by the university authorities. This edict was made to apply to all foreigners, but as the holders of British diplomas were the principal sufferers some of the English journals took the matter up, seemingly very indignant that any government in the world should deny an Englishman the right to do as he pleased. They could not conceive that anyone should question the value of a British diploma, so concluded that the prohibition was not imposed because of mistrust of the competency of the British practitioner, or of the diploma which he might hold, but that it was simply a measure of protection adopted in order to lessen competition against the native doctors and to make business for the Swiss medical schools.

There can be little doubt that that is the true explanation of the action of the Swiss, and also of the French Governments in denying foreign doctors the right to practise without getting a Swiss or a French diploma. The English doctors propose to retaliate in kind, and it is very proper that they should do so, for giving away valuable privileges while getting nothing in return may be very virtuous, but it is not sensible. The principle of reciprocity underlies other questions than that of the tariff. If the Swiss and the French will not accept British diplomas the English are right in refusing to recognize Swiss and French qualifications, and we hope they will persist in their refusal until their own diplomas are recognized in Switzerland and in France.

But why, then, should the English and the French complain, as some have, because their diplomas and licenses are no longer to be recognized as entitling them to practise in the different States of our Union?

A NEW METHOD FOR THE RELIEF OF HERNIA.

Reference was made in these columns a few months ago to a recent paper by Dr. William T. Bull on radical operations for hernia, in which it was shown that the percentage of permanent cures was really quite small, and that the operation gave, in a large proportion of cases, only temporary relief. This was no news to those who have much to do with hernia, however disappointing it may have been to those whose faith rested solely on the reports of enthusiastic operators published before the results of their methods had been put to the test of time. There is, however, no reason to despair of ever attaining a permanent cure of hernia by operative means, merely because the methods hitherto employed have failed to come up to the anticipations of their originators. The possibility of a radical cure of hernia is certainly not beyond a rational and reasonable imagination, and past failures offer no excuse for discouragement or for refusing to study new modes of operating and to compare their results with those obtained by the older methods.

Dr. Edoardo Bassini, of Padua, has recently published a memoir[1] descriptive of a new method devised by himself, by means of which he believes that much more certain and permanent results can be obtained than have yet been by the older operations. The object after which he strives is to restore the inguinal canal as nearly as possible to its normal shape and direction, making it run obliquely as in health, and giving to it its two walls between which the spermatic cord shall pass.

We will describe this operation briefly, omitting of necessity most of the details and the various modifications adopted by the author in order to meet special indications. The aponeurosis of the external oblique, overlying the inguinal canal, and the pillars of the external ring are first exposed. Then, after all bleeding has ceased, the aponeurosis is incised over the whole course of the canal, from the external to the level of the internal ring, and is dissected out from the contiguous structures so as to form two flaps which are folded back to expose fully the underlying tissues. The spermatic cord is now drawn out and separated from the neck of the sac as far back as may be into the inguinal fossa. After this the sac itself is opened, adhesions, if any be present, are broken up, and if there be thickened omentum it is usually excised. The hernia being reduced, the neck of the sac is twisted and ligated, and the portion below the ligature is cut off. This completes the second stage of the operation.

The third step consists in dissecting away from the aponeurosis and adipose layer above and below the outer margin of the rectus muscle and the triple layer formed by the internal oblique and transversus abdominis muscles and Scarpa's fascia. The flap so obtained is now drawn over and attached firmly by interrupted silk sutures to the posterior border of Poupart's ligament, forming thereby the posterior wall of the canal over which runs the spermatic cord. The final stage of the operation consists in reuniting the divided portion of the ex

[1] Nuovo Metodo Operativo per la Cura dell' Ernia Inguinale, pel Dott. Edoardo Bassini, Professore Ordinario di Clinica Chirurgica. Padova. R. Stabilimento Prosperini, 1889.

ternal oblique aponeurosis by interrupted sutures. A new canal is thus formed for the passage of the spermatic cord, and the abdominal wall is able to resist any attempt at redescent of the hernia without the aid of a truss. The external wound is now closed, antiseptic dressings are applied, and the operation is complete.

Dr. Bassini publishes a table of his operations and the results obtained. He had treated 251 cases of non-strangulated hernia, of which 108 remained cured at periods of from one to four and one-half years after the operation. In 131 cases operated upon from a month to a year before the tables were compiled there had also been no relapse. Four patients had been lost sight of, in seven cases there had been a reappearance of the hernia, and one case died of causes unconnected with the operation. Encouraged by these results the author feels justified in bringing his method to the notice of the profession and asking that a trial of it be made by others who may be dissatisfied with the older operations.

News of the Week.

Peptonuria after Koch's Injections.—According to a communication made by Professor Koehler at the last meeting of the Vienna Society of Physicians, the toxic effect of Koch's lymph is marked in some cases by the presence of peptones in the urine of the patients who have been injected. In 33 out of 200 cases the presence of peptones could be tested; also in 2 cases of non-tuberculous patients who had been injected for control, peptonuria occurred after the injection, though no reaction could be observed.

The Efficacy of Koch's Fluid in Tuberculosis of Cattle is about to be tested.

Honors to Medical Men.—Dr. Quain has received a baronetcy, and Professor Humphrey, of Cambridge, has been knighted.

A Curious Field of Work for Women.—Dr. P. N. Parnowskaja, a Russian female medical practitioner, has been awarded a gold medal by the Moscow Society of the Friends of Natural Science, Anthropology, and Ethnography, for her work on the "Anthropology of Prostitutes and Female Thieves."

Miss Garrett's Liberality.—Of the $100,000 raised to endow the Johns Hopkins Medical College, $48,000 was given by Miss Garrett.

A Dispensary for the Treatment of Diseases of Women by Electricity.—A dispensary for the treatment of the diseases of women amenable to electricity has been opened in Philadelphia.

Medicos Under the Microscope.—Under this title the editor of a London lay journal announces a series of special articles intended to serve "as a guide which will steer the neophyte clear of incompetent or semi-incompetent men into the safe harborage of the consulting room of the doctor who combines the essential qualities of ability, experience, and high character." "It must," he adds, "be absolutely understood that the gentlemen whose pen-portraits will be given, have in no way assisted at, or even consented to their own delineation."

A New Journal Devoted to Koch's Treatment.—From January 1, 1891, a new journal is announced to appear under the title "Central Zeitung für das Koch'sche Heilverfahren." It is to be devoted, as the name implies, to anything pertaining to the cure of tuberculosis and other infective diseases.

The Longest Medical Courses are given at the Buddhist's Lamas' University in Thibet. The student has to study for ten years. According to *Nature*, a traveller named Ptitsyn has returned from that country with a collection of medical books and drugs illustrative of the knowledge and the methods of practice in Thibet. Mr. Ptitsyn remarks that he has found over one hundred diseases described in the Buddhist literature, and of these a mythical origin is ascribed to only two. Strictly medical subjects are not studied until the fifth year of the course, the first four years being devoted to the study of the languages and theology. The eighth year is devoted to astrology, and philosophy is studied in the last two years.

Surgery and Exact Science.—The late Professor Syme was in the habit of expressing his opinion that surgery would never be an exact science, and that perfection was unattainable, because silly folks were always trying to invent new plans of treatment to replace the sadly few absolutely successful methods. One of his examples used to be the treatment of hydrocele by injections of iodine; another the ligature of the superficial femoral for popliteal aneurism. His views receive curious confirmation, for in the *Medical News* of Philadelphia, received November 29th, we find a paper on the alarming and fatal results following attempts at the radical cure of hydrocele; and in the *British Medical Journal* of same day a paragraph, by a young surgeon, advising ligature of the popliteal instead of ligature of the superficial femoral for popliteal aneurism.—*Edinburgh Medical Journal.*

Proposed Medical Legislation in Pennsylvania.—The present registration law of Pennsylvania is said to be almost a total failure. According to the *Times and Register* another attempt will be made during the coming session of the Pennsylvania Legislature to procure the passage of an act creating a Board of Medical Examiners. The proposed bill places the appointment of members entirely in the hands of the governor; the only restrictions to his choice being those relating to legality and date of graduation, and freedom from alliances with medical colleges. A new clause provides that no two of the nine examiners shall be residents in the same county. This opens the field to the country members, and cuts Philadelphia, with her 2,000 physicians out of 8,000 in the State, down to a single representative.

Bequests to Charities.—The late Mrs. Elizabeth P. Fogg has bequeathed to the New York Hospital, $20,000, and to the Metropolitan Throat Hospital, $10,000.

A New Diploma Mill, called the "Union Medical Institute," has been discovered at Newburg. Its diplomas are offered for $50.—*Medical Standard.*

A Versatile Practitioner.—The following advertisement appears in the columns of an English newspaper: Michael Keena, of Friarstown, Parish of Meedin, four miles from Tyrrellspass, four from Rochford Bridge, three from Castletown-Geoghegan. I propose to cure by herbs — water gravel, kidney gravel, rheumatism, blast piles inwardly and outwardly, falling sickness, any person wishes to have the blight stopped on their potatoes, the toothache, soft and hard corns. If you wish to have your hens laying in winter, apply to me.

A Hygienic Institute for Philadelphia.—A contract has been signed for the erection of a building for hygienic instruction, as an annex to the University of Pennsylvania, to cost $50,000. The entire expense will be borne by Henry C. Lea, and it will be the finest structure of the kind in America, and the finest hygienic institution in the world. The building is to occupy a space of 160 by 182 feet. It will have fifty windows to each floor, and the plumbing and other sanitary arrangements are to be perfect.

The Production of Immunity from Diphtheria.—Drs. E. A. Von Schweinitz and W. M. Gray, of Washington, D. C., write to the *Medical News* that they have succeeded in obtaining a chemical substance which renders guinea-pigs treated with it insusceptible to diphtheria upon subsequent introduction of the strong virus into the system, while the control guinea-pigs died in from twenty-four to forty eight hours. They further believe that the experiments being made will demonstrate that we have a substance which will serve to control or prevent diphtheria in man.

Bulletin of the American Academy of Medicine.—The Academy has adopted the excellent plan of publishing occasional bulletins containing reports of special work. The first issue contains the abstract of a report on the comparative value of the academical degrees in our American colleges. This report shows that the degree of A.B. in America is given by at least three hundred and forty-two institutions, and that there is as much difference in the requirements for graduation as there is among medical colleges. This fact is so strikingly true that the committee recommends to the Academy the adoption of a standard for the degree of A.B., below which standard no diploma will be recognized.

The Hypodermic Injection of Oxygen.—Dr. Francesco Valenzuela, physician to the Provincial Hospital, Madrid, has just published in *El Siglo Médico* a paper on new methods of administering oxygen, with especial reference to the treatment of senile pneumonia. Believing that oxygen inhaled in dyspnœa fails frequently to relieve because it does not come in contact with a sufficiently large vascular surface, he began administering the gas per rectum and also hypodermically. In every case in which the oxygen enema was given the dyspnœa was relieved in a decided and permanent manner. The ease and rapidity with which the gas was absorbed by the intestine were very remarkable. Oxygen, indeed, appeared to be as readily taken up by the intestine as by the lungs, four injections of five litres each being absorbed in an hour, thus proving the intestinal mucous membrane to be capable of serving as a most valuable adjunct to that of the lungs. In employing oxygen hypodermically Dr. Valenzuela believes it to be important to introduce the gas in its nascent state. The situation selected for the puncture was the arm, and the quantity of gas introduced varied from half a litre to a litre. Cellular emphysema was of course produced, and a sensation of heat was complained of, but both disappeared entirely in the course of a few hours. There was no calmative action or slowing of the respiration, but there was a marked stimulating action on the heart, such as is indicated in the collapse that follows pneumonia or fevers of a typhoid character, also in cerebral congestion and asphyxia. No indication is given of the temperature at which the oxygen is introduced, a point which, according to Dr. B. W. Richardson, is of great importance. Perhaps the Spanish observer, who does not appear to be aware of Dr. Richardson's work, is mistaken in ascribing the advantage gained by using oxygen prepared *ad hoc* to its being nascent, whereas it is probably due to the temperature being high. It will be noted that Dr. Valenzuela confirms Dr. Richardson's statement that oxygen is relaxant and eliminative.—*The Lancet.*

The Hospital Sunday Collections this year have so far amounted to nearly forty thousand dollars.

Chicago as a Place for Doctors.—The secretary of the Illinois State Board of Health, in his recent quarterly report, states that there has never been such a rush of medical men to Chicago as during the past three months. More than two-thirds of the certificates issued were to physicians who wished to practise in Chicago. And never before in the same length of time have so many professional frauds attempted to obtain a foothold in Chicago. It is evident that the increase of population, and especially the coming World's Fair, are the attractions. Eleven applicants were refused licenses because they had diplomas from schools not in good standing, because their professional records had been tarnished elsewhere, or because they could not comply with the requirements of the Board. The anxiety to settle in Chicago is also manifest in the incorporation of so called medical companies, medical associations, and dispensaries, thus taking advantage of the lax laws and attempting to evade the Medical Practice Act. New York, not having the World's Fair, will take pleasure in sending on her medical men that will not be missed here.

Chair of Otology in the University of Pennsylvania.—Dr. Burton Alexander Randall has been appointed Clinical Professor of Otology in the University, to succeed Dr. George Strawbridge, who resigned some months ago on account of ill health.

German Congress of Internal Medicine.—The Tenth Congress of Internal Medicine will be held at Wiesbaden from April 6th to 9th, 1891, under the presidency of Professor Leyden, of Berlin. Among the subjects already in the programme are the following: "Gall-stones" (to be introduced by Professor Naunyn, of Strassburg, and Fürbringer, of Berlin); and "Angina Pectoris" (to be introduced by Dr. A. Fraenkel, of Berlin, and Dr. O. Vierordt, of Heidelberg). Addresses will also be delivered by Dr. T. Schott, of Nauheim, on the "Differential Diagnosis of Pericardial Exudation and Dilatation of the Heart;" and by Professor Kahler, of Vienna, on "Intermittent Albuminuria."

THE COMPOSITION OF KOCH'S LYMPH.

What Professor Koch Says It is, and What It Can Do.

(By Cable to the MEDICAL RECORD.)

BERLIN, January 15, 1891.

THE curiosity to know the composition of the famous lymph has been gratified by the publication to-day of an article by Professor Koch on the subject. In the following, as will be seen, he reaffirms his original convictions and acknowledges the valuable assistance he has received from those who have used his fluid, and thus helped him in the accumulation of experience.

Professor Koch says: Two months ago I published the results of my experiments with the new remedy for tuberculosis, since which time many physicians who received the preparation have been enabled to become acquainted with its properties through their own experiments. So far as I have been able to review the statements published and the communications received by letter, my predictions have been fully and completely confirmed. The general consensus of opinion is that the remedy has a specific action upon tubercular tissues, and is, therefore, applicable as a very delicate and sure reagent for discovering latent and diagnosing doubtful tuberculous processes. Regarding the curative effects of the remedy, most reports agree that, despite the comparatively short duration of its application, many patients have shown more or less pronounced improvement. It has been affirmed that in not a few cases even a cure has been established. Standing quite by itself is the assertion that the remedy may not only be dangerous in cases which have advanced too far —a fact which may forthwith be conceded- but also that it actually promotes the tuberculous process, being therefore injurious.

During the past six weeks I myself have had opportunity to bring together further experiences touching the curative effects and diagnostic application of the remedy in the cases of about one hundred and fifty sufferers from tuberculosis of the most varied types in this city and in the Moabit Hospital. I can only say that everything I have latterly seen accords with my previous observations. There has been nothing to modify in what I before reported. As long as it was only a question of proving the accuracy of my indications it was needless for anyone to know what the remedy contained or whence it was derived. On the contrary, subsequent testing would necessarily be more unbiassed the less people knew of the remedy itself. Now, after sufficient confirmatory testing, the importance of the remedy is proved, my next task is to extend my study of the remedy beyond the field where it has hitherto been applied, and if possible to apply the principle underlying the discovery to other diseases.

This task naturally demands a full knowledge of the remedy. I therefore consider that the time has arrived when the requisite indications in this direction shall be made. This is done in what follows.

Before going into the remedy itself, I deem it necessary for the better understanding of its mode of operation to state briefly the way by which I arrived at the discovery. If a healthy guinea-pig be inoculated with the pure cultivation of German Kultur of tubercle bacilli, the wound caused by the inoculation mostly closes over with a sticky matter and appears, in its early days, to heal. Only after ten to fourteen days a hard nodule presents itself, which, soon breaking, forms an ulcerating sore, which continues until the animal dies. Quite a different condition of things occurs when a guinea-pig already suffering from tuberculosis is inoculated. An animal successfully inoculated from four to six weeks before is best adapted for this purpose. In such an animal the small indentation assumes the same sticky covering at the beginning, but no nodule form. On the contrary, on the day following, or the second day after the inoculation the place where the lymph is injected shows a strange change. It becomes hard and assumes a darker coloring, which is not confined to the inoculation spot but spreads to the neighboring parts until it attains a diameter of from 0.05 to 1 ctm.

In a few days it becomes more and more manifest that the skin thus changed is necrotic, finally falling off, leaving a flat ulceration which usually heals rapidly and permanently without any involvement of the adjacent lymphatic glands. Thus the injected tubercular bacilli quite differently affect the skin of a healthy guinea-pig from one affected with tuberculosis. This effect is not exclusively produced with living tubercular bacilli, but is also observed with the dead bacilli, the result being the same whether, as I discovered by experiments at the outset, the bacilli are killed by a somewhat prolonged application of a low temperature or boiling heat or by means of certain chemicals. This peculiar fact I followed up in all directions and this further result was obtained—that killed pure cultivations of tubercular bacilli, after rinsing in water, might be injected in great quantities under healthy guinea-pigs' skin without anything occurring beyond local suppuration. Such injections belong to the simplest and surest means of producing suppuration free from living bacteria.

Tuberculous guinea-pigs, on the other hand, are killed by the injection of very small quantities of such diluted cultivations. In fact, within six to forty-eight hours, according to the strength of the dose, an injection which is not sufficient to produce the death of the animal may cause extended necrosis to the skin in the vicinity of the place of injection. If the dilution is still further diluted until it is scarcely visibly clouded, the animals inoculated remain alive and a noticeable improvement in their condition soon supervenes. If the injections are continued at intervals of from one to two days, the ulcerating inoculation wound becomes smaller and finally scars over, which otherwise it never does; the size of the swollen lymphatic glands is reduced, the body becomes better nourished, and the morbid process ceases, unless it has gone too far, in which case the animal perishes from exhaustion. By this means the basis of a curative process against tuberculosis was established.

Against the practical application of such dilutions of dead tubercle bacilli there presented itself the fact that the tubercle bacilli are not absorbed at the inoculation points, nor do they disappear in another way, but for a long time remain unchanged, and engender greater or smaller suppurative foci. Anything, therefore, intended to exercise a healing effect on the tuberculous process, must be a soluble substance which would be liberated to a certain extent by the fluids of the body floating around

the tubercle bacilli, and be transferred in a fairly rapid manner to the juices of the body; while the substance producing suppuration apparently remains behind in the tubercular bacilli, or dissolves but very slowly. The only important point was, therefore, to induce outside the body the process going on inside, if possible, and to extract from the tubercular bacilli alone the curative substance. This demanded time and toil, until I finally succeeded, with the aid of a forty to fifty per cent. solution of glycerine, in obtaining an effective substance from the tubercular bacilli. With the fluid so obtained I made further experiments on animals, and finally on human beings. These fluids were given to other physicians to enable them to repeat the experiments.

The remedy which is used in the new treatment consists of a glycerine extract, derived from the pure cultivation of tubercle bacilli. Into the simple extract there naturally passes from the tubercular bacilli, besides the effective substance, all the other matter soluble in fifty per cent. glycerine.

Consequently, it contains a certain quantity of mineral salts, coloring substances, and other unknown extractive matters. Some of these substances can be removed from it tolerably easily. The effective substance is insoluble in absolute alcohol. It can be precipitated by it, though not, indeed, in a pure condition, but still combined with the other extractive matter. It is likewise insoluble in alcohol. The coloring matter may also be removed, rendering it possible to obtain from the extract a colorless, dry substance containing the effective principle in a much more concentrated form than the original glycerine solution. For application in practice this purification of the glycerine extract offers no advantage, because the substances so eliminated are unessential for the human organism. The process of purification would make the cost of the remedy unnecessarily high.

Regarding the constitution of the more effective substances, only surmises may for the present be expressed. It appears to me to be derivative from albuminous bodies, having a close affinity to them. It does not belong to the group of so-called toxalbumins, because it bears high temperatures, and in the dialyzer goes easily and quickly through the membrane. The proportion of the substance in the extract to all appearance is very small. It is estimated at fractions of one per cent, which, if correct, we should have to do with a matter whose effects upon organisms attacked with tuberculosis goes far beyond what is known to us of the strongest drugs.

Regarding the manner in which the specific action of the remedy on tuberculous tissue is to be represented various hypotheses may naturally be put forward. Without wishing to affirm that my view affords the best explanation, I represent the process myself in the following manner: The tubercle bacilli produced when growing in living tissues, the same as in artificial cultivations, contain certain substances which variously and notably unfavorably influence living elements in their vicinity. Among these is a substance which in a certain degree of concentration kills or so alters living protoplasm that it passes into a condition that Weigert describes as coagulation necrosis. In tissue thus become necrotic the bacillus finds such unfavorable conditions of nourishment that it can grow no more and sometimes dies.

This explains the remarkable phenomenon that in organs newly attacked with tuberculosis, for instance in guinea-pigs' spleen and liver, which then are covered with gray nodules, numbers of bacilli are found, whereas they are rare or wholly absent when the enormously enlarged spleen consists almost entirely of whitish substance in a condition of coagulation necrosis, such as is often found in cases of natural death in tuberculous guinea-pigs. The single bacillus cannot, therefore, induce necrosis at a great distance, for as soon as necrosis attains a certain extension the growth of the bacillus subsides and therewith the production of the necrotizing substance. A kind of reciprocal compensation thus occurs, causing the vegetation of isolated bacilli to remain so extraordinarily restricted, as, for instance, in lupus and scrofulous glands.

In such cases the necrosis generally extends only to a part of the cells, which then, with further growth, assumes the peculiar form of riesen zelle, or giant cell. Thus, in this interpretation, follow first the explanation Weigert gives of the production of giant cells.

If now one increased artificially in the vicinity of the bacillus the amount of necrotizing substance in the tissue the necrosis would spread a greater distance. The conditions of nourishment for the bacillus would thereby become more unfavorable than usual.

In the first place the tissue which had become necrotic over a larger extent would decay and detach itself, and where such were possible would carry off the inclosed bacilli and eject them outwardly, so far disturbing their vegetation that they would much more speedily be killed than under ordinary circumstances.

It is just in looking at such changes that the effect of the remedy appears to consist. It contains a certain quantity of necrotizing substance, a correspondingly large dose of which injures certain tissue elements even in a healthy person, and perhaps the white blood-corpuscles or adjacent cells, thereby producing fever and a complication of symptoms, whereas with tuberculous patients a much smaller quantity suffices to induce at certain places, namely, where tubercle bacilli are vegetating and have already impregnated the adjacent region with the same necrotizing matter, more or less extensive necrosis of the cells, with the phenomena in the whole organism which result from and are connected with it.

For the present, at least, it is impossible to explain the specific influence which the remedy, in accurately defined doses, exercises upon tuberculous tissue, and the possibility of increasing the doses with such remarkable rapidity, and the remedial effects which have unquestionably been produced under not too favorable circumstances.

Of the consumptive patients whom he described as temporarily cured two have been returned to the Moabit Hospital for further observation.

No bacilli have appeared in their sputum for the past three months, and their phthisical symptoms have gradually and completely disappeared.

Cold Weather and High Death-rate.—The cold weather in England has raised the death-rate in London to thirty per thousand.

THE LYMPH TREATMENT IN NEW YORK.

CASES AT ST. LUKE'S HOSPITAL.

Service of Dr. Francis P. Kinnicutt.

Case X.—Male, aged fourteen. Transferred by Dr. Gibney from the Hospital for Ruptured and Crippled, for treatment by inoculations, December 15th.

Previous History.[1]—Patient has always been delicate. In February, 1890, "left ankle was sprained" in jumping from cart. Much swelling followed and ankle remained swollen and painful up to the date of admission to hospital in October of same year. Ten days previous to admission a spontaneous evacuation of pus occurred.

Examination on Admission.—There is a marked bony enlargement of the lower end of both tibia and fibula (left), with local heat and sensitiveness. On inner surface of tibia, just above ankle joint, there is an ulcer three-quarters of an inch in diameter, and another, somewhat smaller, on outer surface of fibula, from both of which there is considerable purulent discharge. The joint is apparently free from disease. Recommended for operation.

Examination Immediately Prior to First Inoculation.—Patient is anæmic. Examination of lungs, heart, liver, and spleen negative. Examination of urine negative. Temperature normal. There are three cicatrices in left cervical region. Suppuration of glands and spontaneous evacuation occurred at the above points, at intervals, during the past three years. Enlarged insensitive glands are present in both axillæ. There is enlargement of the lower end of both the tibia and fibula (left), with indolent ulcers, of about the size of an English shilling, over the outer and inner aspects respectively of the swelling. There is a scanty, thin, purulent discharge from these. The ankle-joint is evidently not involved, motion in all directions being free and painless.

Inoculations were made on December 16th, 18th, 20th, and 23d of 0.0005 gm., 0.0005 gm., 0.001 gm., and 0.001 gm. They were followed by very moderate systemic and local reactions, the highest temperature recorded being 101⅛° F. The local signs consisted in slightly increased swelling, pain, and sensitiveness at the site of obvious disease. The purulent discharge from the ulcers became more copious and consistent. The temperature in the intervals between the inoculations fell to normal.

A fifth inoculation of 0.0015 gm. was made on December 27th. A sharp general reaction followed, the temperature reaching 102⅘° F., with sweating, headache, etc. There was also greatly increased swelling, pain, and sensitiveness, with reddening of the skin, at the site of disease. A marked swelling of the head of the tibia of the other leg, with pain and sensitiveness, followed; also a doughy swelling, with pain, was developed over the scaphoid bone of the right foot and the enlarged axillary glands became more swollen and painful. A very free discharge of creamy pus occurred from both ulcers and there was much undermining of the contiguous skin. No necrosed bone, however, could be detected by the probe. A copious purulent discharge has continued up to the present date and the other local signs have persisted in the absence of further inoculations. The axillary glands remain swollen and painful. There is moderate continuous pyrexia, with irregular diurnal variations.

The above history presents several points of great interest. The slight effect of the first inoculations is to be noted, and the development, on their repetition in increased strength, of signs of disease in bones in which disease previously had not been suspected. Close questioning, however, elicited the fact that pain had been felt at times during the past three months, both in the head of the tibia and in the right foot, and on one occasion, after a slight strain, temporary swelling had been noticed at the former site. The effect of the inoculations has evidently been to excite an active inflammatory process in tuberculous tissues previously comparatively quiescent.

Inasmuch as appreciable signs pointing to the existence of disease elsewhere than in the lower epiphyses of the tibia and fibula were absent before inoculation, the possibility of promoting cure by absolute rest in structures in which disease was present though quiescent need not be considered.

It is in such cases that the value of the lymph is conspicuous. Latent disease, which we thereby are precluded from treating, but in which there is the ever-present danger of further infection, becomes manifest and offers opportunities for relief, either by medical or surgical means. The records of orthopædic hospitals are filled with histories of cases more or less similar to the above, in which the ultimate issue is general infection and death.

The course apparently indicated in the above case, with our present knowledge of the action of the lymph, is a repetition of the inoculations until failure of reaction points to the probable death of all tuberculous tissue and the subsequent removal of such tissue by surgical means.

[1] I am indebted to Dr. Samuel Smith, the House Surgeon of the Hospital for Ruptured and Crippled, for the above notes.

CASES AT THE ST. JOSEPH'S ORPHAN ASYLUM.

Service of Dr. Edmund Charles Wendt.

General Remarks.—Two new cases have received inoculations during the past week, making the total number of cases fourteen. All the old cases except one have been subjected to reinoculations, and remain under observation. With the exception of two cases in which rather violent symptoms occurred, the reactions, especially as to rise of temperature, have been less marked. It would appear that children develop tolerance to the lymph quite as rapidly as adults. In some cases the pulse was noticed to become quicker and feeble, but anything like alarming collapse has not been observed. It is to be remembered in this connection that the dosage of the lymph is still comparatively small, the largest quantity injected at any one time having been 0.007 gm. Brief references to some of the cases are appended.

Case I., of last report.—This girl's only sister died of phthisis during the week, and there is reason to believe that she herself is already attacked. Finely crepitant râles were heard January 10th on deep inspiration over left upper portion of lung. The febrile reactions following injections have not exceeded 102° F. The dose of lymph is now up to 0.006 gm. Her appetite and general condition are at present better than before treatment was begun. Only occasional slight cough. No expectoration.

Case II., of previous report.—Injections up to 0.007 gm. on January 6th, 8th, 9th, and 11th. Reactions to 102° F. and 103° F., with rapid defervescence to normal temperature. Glands smaller, but show absolutely no local reaction. Erysipelatoid redness around nose several times, quickly subsiding. Nose less thick than formerly. Only slight fetor from ozæna.

Case V.—This girl still reacts rather violently, although the doses of lymph are small.

January 6th, 0.002 gm.; 8th, 0.003 gm.; 11th, 0.0035 gm. On January 10th fine and large crepitant râles were heard for the first time over entire left side of thorax, both in front and behind. After the last injection her gait became staggering, she grew very nervous and restless. Pulse ran up to 160, quite feeble; temperature, 104.2° F. This girl had chorea.

January 12th. Temperature fluctuated between 101.6° F. and 103° F. all day.

January 13th. Temperature 98.2° F. at 11 A.M.

Case VI., of last report.—In this case the lymph also produces rather violent symptoms in small doses, up to 0.0045 gm. Temperature rose to 105.8° F., on January

8th, after an injection of 0.004 gm. Defervescence gradual, and return to normal point only after thirty-six or forty-eight hours. Violent headache and backache were complained of. Pulse weak, appetite impaired. Râles quite variable in extent, changing from day to day. Dry cough. No expectoration.

On January 11th last injection. January 13th, temperature all morning, 97.2° F. Temperatures are always taken in the rectum.

Case VIII., of previous report.—Moderate reactions. Scarlatinal rash has followed every new injection. Supraclavicular glands unmistakably smaller. Slight cough, but no râles.

Case IX., of previous report.—Inoculations, January 8th, 9th, 10th, and 12th, up to 0.002 gm. Reactions moderate up to 102.8° F., on January 10th, and 102.4° F. on January 12th. Subnormal morning temperature has been observed. The corneal opacities are less dense. Ulcerative processes of skin improved.

Case X., of previous report.—January 7th, 9th, and 12th, injections up to 0.002 gm. Has vomited several times. Râles are now audible over several regions of thorax. Scarcely any cough. Highest temperature, 101° F., twenty hours after last inoculation. Temperature in rectum, 98° F. at time of last injection.

crust formation. Glands unaffected. Slight febrile reactions after third and fourth injections. Highest temperature 100.6° F.

Case XIV. *Suspicious Apices, Phthisical Thorax, Cutaneous Ulcerations, Lymphadenitis.*—Boy, aged thirteen. Brother of Case IX. Very flat chested. Retraction of supra- and infra-clavicular region. Harsh breathing at apices. Slight dulness on percussion there. No râles. No cough. Ulcerations about nose and eyes. Glands, under jaw on left side, almond size.

January 11th.—Injection of 0.00025 gm. No reaction.

January 12th.—Injection of 0.00055 gm. Temperature rose to 102° F. in six hours.

January 13th.—Temperature only receded to 100.8° F. this morning.

CASES AT THE MONTEFIORE HOME FOR CHRONIC INVALIDS.

Service of Dr. Simon Baruch.

(Dr. Max Rosenthal, Resident Physician.)

The following table furnishes a graphic statement of the reactions produced by the injections; also the changes of weight during three weeks' treatment.

* 99.4° F. before injection. † 100° F. before injection.

Note.—All these cases are phthisis, except 8 and 9, which are skin and bone tuberculosis.

Case XI., of previous report.—Injections January 7th, 8th, 9th, 11th, and 12th, up to 0.003 gm. Very slight reaction. Temperature fluctuating between 98.4° F. and 100.4° F. Severe headache. A few râles have become audible, otherwise no change in her condition.

Case XII., of previous report.—Injections January 7th, 8th, 9th, and 10th, up to 0.003 gm. Ulcerative cutaneous processes rapidly healing, but glandular enlargement shows no decrease in size. Slight cough, but no râles. Nausea and general symptoms moderately severe, but febrile reaction very slight. Highest temperature 100.4° F.

The two cases which follow are new cases.

Case XIII. *Scrofulous Ulcerations of the Neck, Chin, Lips, and Nose. Lymphadenitis.* — Family history unknown. Fairly well nourished boy. Extensive cutaneous ulcerations of superficial character, moist eczematous patches. Lungs negative. No cough. Injections January 9th, 10th, 11th, and 12th, up to 0.002 gm. A diffuse redness developed around ulcerative spots. Rapid

The following brief histories may be of interest. As the observations have been made with great care, they offer food for reflection:

Case I. (Table).—I. D——, aged thirty-six, admitted November 3, 1889. Has coughed for two years; hæmoptysis during the past two years four times; the last in April, 1889; was treated at Mt. Sinai Hospital. On entrance had involvement of the left apex with friction râles on right side, enlarged liver, and a weak heart. Had night-sweats, coughed a good deal, and expectorated mostly mucous sputa. Was treated the last year only by hydrotherapy (at first wash-off, then wet sheet, and then rain-bath 65° F., for thirty to forty seconds). On entrance, weight 162½ pounds. Condition before injections: Weight 178. Slight loss of resonance at left apex. Bacilli few; ten on cover glass. Breathing good, few fine friction râles over the left apex and over a small spot on the right side in the axillary line. Heart-sounds normal but weak. No cough and no expectoration. Was con

sidered as practically cured. Temperature always normal. November 16th, first injection of Koch's lymph. One milligramme produced a strong reaction. Temperature rose to 102°, went down to 98.3° F.

Injections having been carried up to 4 milligr., temperature rose to 103.8° F., and there was distinct local reaction, manifest by bronchia respiration and voice, which subsided in two days, with return of normal temperature. This case is a flagrant example of the elective affinity of the lymph for tuberculous tissue. Dr. Hodenpyl reports "a very few bacilli, two on the cover glass" (after three and a half weeks' treatment).

This patient has lost five pounds.

Case V.—B. F——, aged twenty eight; admitted July 7, 1890; pedlar, single. Last winter caught a cold, and since then coughs. In March cough became more troublesome, expectorated a great deal mucous sputa; night-sweats. He became very weak, gave his work up, and went to Mt. Sinai Hospital, where his sputa were a few times mixed with blood; never had hæmoptysis. He improved in Mt. Sinai, and was sent to the Home. On entrance complains of pain on both sides of chest; coughs mostly in daytime; expectorates very little; night-sweats; feels weak, and does not sleep well. Weight, 115 pounds. Was treated by rain bath, 65° F., creasote, and cod-liver oil. Physical signs on entrance: Tympanitic dulness in the upper third of the left lung, with bronchovesicular respiration and a few bubbling râles two inches below the clavicle. Right side, exaggerated vesicular respiration, with prolonged expiration, and a few friction râles. At present (one day before injections) no bacilli found in sputum, although they had been previously present; hardly any cough or expectoration, no night-sweats, feels much stronger; complains only of pain on both sides of the sternum. Physical signs without change. Although this case had been steadily improving, having gained twenty-one pounds, he has lost one pound and a half since the injections. In contrast to these two cases in the first stage, I submit three advanced cases which have improved in weight under the injections.

Case VI. (Table). — B. S——, aged eighteen, admitted November 12, 1890. Parents died of phthisis. Has been coughing one year and four months, since he had pneumonia. Pain in left chest; night sweats; dulness (tympanitic) over left apex; bubbling râles and bronchial breathing distinct for one inch below clavicle. Weight, 115 pounds. Treatment: Rain-bath, 65° F., for thirty seconds daily; creasote. December 16th, day before injection, weighs 123 pounds (increase of eight pounds in one month). Physical signs clearly point to existence of small cavity; cough and expectoration less; bacilli present; temperature normal during the past three weeks, although to-day (December 30th) there are physical signs of activity in the local process; his reaction has so far ceased that he received 5 milligr. Bacilli not changed; are rather longer than usual. He coughs and expectorates less, and has gained four pounds—the largest increase noted. The progress of this boy is remarkable.

Case XVIII. (Table).—E. W——, aged twenty-nine. Illness began three and one-half years ago with hæmoptysis and cough. She has albuminuria. Cracked-pot sound over small area at left apex, front; prolonged expiration and tubular breathing. Dulness over same area. Yellow-green sputa. Weight, 130 pounds, now 131½ pounds. Has been treated by sweat-box, rain baths, and creasote. Now has scarcely any cough or expectoration. Temperature normal in mouth. Examined before injection: Dulness over apex, right side, with mucous râles. Since injection she has had chills; vomited twice; cough more troublesome; physical signs more pronounced during reaction; crepitant râles heard now for the first time. Despite these symptoms she has gained two pounds, which she has lost during the past week.

Case II.—G——. Another case which has distinct evidence of a cavity, on account of which hydrotherapy had been discontinued, and which was injected only because of his anticipation of a successful result, and so cautiously that I began with ½ milligr. Has steadily improved in every symptom, while the physical signs denote activity in the local process. He has gained one pound and a half; is cheerful and improved in appearance. It is evident from my observations during the past two weeks that there are many unexpected results arising from the lymph, whose potency is thus most emphatically attested. Not a single case of phthisis has thus far resisted its reactive influence.

Case IX.—E——. A case of old fistulous tract, with great infiltration, resulting from an old mastoid abscess, that has been the bane and puzzle of many surgeons, was sent to us, as are most other cases, to spend his last days in peace. A gradual advance failed to produce reaction until 5¼ milligr. were reached, which produced a reaction that has subsided. He had been regarded by the house physician as too feeble to be again injected. When I examined him two weeks afterward, I found to my great surprise a complete removal of the dirty slough which had covered the tuberculous infiltration, and whose stench had resisted all deodorizing efforts. He was again injected. Dr. Dennis, in whose surgical service he had been for a long time, examined him last Saturday, and in the presence of a large class of students expressed his astonishment at finding this ulcer, which had resisted all treatment, almost completely cicatrized under the lymph treatment. As a diagnostic proof, this case is as unique as is Case I. (phthisis). The ultimate result will be a crucial test in both cases.

I offer these clinical facts for study and comparison. Without making positive general deductions, it may be stated that Professor Koch has offered three propositions:

1. That the lymph has an elective affinity for tuberculous tissue.

2. That it produces necrosis of this tissue accompanied by a process of exfoliation or extension of the dead from the living normal tissue.

3. That the removal of the necrosed tissue with its contained bacilli must be accomplished by surgery or by the efforts of the system, aided by the means hitherto in vogue.

I hold that the first two propositions have been fully and positively verified by my experiments, and that therefore the last may be regarded as presenting a favorable prognosis.

I am indebted to Drs. Hodenpyl and Ettinger for aid in sputa examinations. Since December 27th Drs. Morjé and Einhorn have had charge of Cases XIII. to XXI. of this table. All the cases I have experimented on were obtained from Dr. Morjé's service.

Hasty Medical Legislation.—A medical law has been passed by the new State of Washington, which in the short space of six months has already developed curiosities. A law was passed that all persons before practising medicine should be examined and licensed by a State board, appointed by the Governor. The Governor appointed on the board four regular practitioners, three homœopaths, a "physio-medic," and an eclectic. It is difficult to learn what a "physio-medic" is. The irregulars combined, elected their candidate president of the board, and placed such other members as they pleased in office. The board adopted rules to the effect that a general average of sixty-five must be made by all but old graduates (of at least five years' standing), who need not average as high in chemistry, physiology, or anatomy as graduates of less than five years' standing. Each member of the board was given subjects on which to prepare questions in writing. Some of these questions have gone the rounds of the medical press as jokes, as for instance one asked by the eclectic, "What is the effect of too much red blood-corpuscles in the blood?"—*Boston Medical and Surgical Journal.*

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 18, 1890.

ALFRED L. LOOMIS, M.D., PRESIDENT, IN THE CHAIR.

Certain Lesions of the Visual Tract from the Eyeball to the Cerebral Cortex.—This was the subject for discussion before the Academy, referred under the rules from the Section on Ophthalmology and Otology, of which Dr. H. D. Noyes was Chairman.

Papillitis.—DR. CHARLES S. BULL read the first paper, which treated of this phase of the general subject. The appearance of the fundus under the ophthalmoscope was described. There came under view the termination of an artery and the beginning of a vein; the ending of the optic nerve, which, owing to its proximity to the brain and certain other circumstances, underwent significant changes in various disease of the brain, cord, and some systemic diseases; further, the retina and a ring of the sclerotic were seen.

He thought the tendency had been to overestimate the significance of the blood-supply to the eye being common with that of the brain. The elasticity of the bed of the vessels as they passed through the sinus in the skull, and their anastomosis with the facial, prevented any close correspondence between intra-cranial and intra-ocular circulation. Mention was made of the influence on the circulation in the retinal vessels by aortic regurgitation, hypertrophy of the left ventricle, and other conditions of the heart, as well as of thrombosis, of severe muscular exercise, cough, epileptic fits, etc. In some of these conditions these retinal veins might become greatly congested. Extravasated blood was rarely seen except in rupture of the vessel. The causes of this were two, namely, increased vascular pressure, and decreased strength in the vascular wall. High arterial tension was often the only apparent cause of retinal hemorrhages. They might occur in senile vascular degeneration, in diabetes, malarial fever, pyæmia, purpura, etc. The central retinal artery was not infrequently the seat of embolism, and was sometimes the first symptom to be observed in disease of the heart. When the obstruction was complete and no collateral circulation was established, only a white line might be left to indicate the position of the vessel. The change in appearance might be sudden or gradual, and remain permanently or a shorter or longer time.

The author then gave his attention to the optic nerve, whose terminal fibres radiated out on the retina, being more numerous on the inside, above and below, than on the temporal side. Its color, observed through the ophthalmoscope, was usually paler than the rest of the disk, the boundary of the disk was the choroidal ring. A narrow rim of the sclerotic was seen within the choroidal ring. There were certain pathological changes occurring in the eye common both to the optic nerve and retina, yet optic neuritis might be independent of disease of the retina. He used the term papillitis that confusion might be avoided. It should be restricted to cases in which the swelling, redness, and opacity were sufficient to obscure the edge of the disk. A description of the appearances in conditions ranging from increased vascularity to marked inflammation of the papilla was given. Papillitis might disappear after having reached a stage in which the veins had been tortuous, dilated, the arteries narrower, or both arteries and veins concealed by œdematous swelling—occasional white patches concealed by a small hemorrhage; or it might go on to show numerous hemorrhages and further changes. Inflammation of the disk, or papillitis, might remain for weeks, months, or even years, in the lower degrees, unchanged, or the more intense changes might take place within a week. In the more severe forms the sight was always impaired, and might be entirely lost. Impairment of vision was commonly more marked in one eye than in the other, and might come on slowly or suddenly. In some cases defect in the field of vision due to intra-cranial disease might be accompanied by peripheral limitation of the field due to papillitis. There was defect in field perception for colors. Some authors were of the opinion that loss of vision following intra-cranial disease was more frequent in descending neuritis than in cases of isolated neuritis. This might be true, but it was exceedingly difficult to distinguish between papillitis due to descending neuritis and purely isolated papillitis. Loss of vision from isolated papillitis alone was never sudden.

Causes of Papillitis.—The most common cause was intra-cranial disease, particularly tumors. Besides tumors there was meningitis at the base, hydatid disease, softening from thrombosis or embolism. Papillitis sometimes occurred in acute diseases of the spinal cord; also in systemic diseases, such as Bright's, febrile disorders, anæmia, etc. It might be excited by great mental disturbance and prolonged exposure.

After reviewing the several explanations which had been given for the occurrence of optic neuritis in connection with intra-cranial disease, the author reached the following conclusions on this point: 1. In cerebral tumors evidence of descending inflammation could be traced in the sheath or in the nerve much more commonly than was generally supposed, while in meningitis the evidence of descending degeneration was almost invariable. 2. Papillitis, more or less intense, might be present while we remained ignorant of its cause. 3. When the cause was mechanical, the pressure did not always lie behind the ring, but might be within the papilla. 4. Slightly increased intra-cranial pressure did not affect the retinal vessels, but sudden pressure might intensify a papillitis originating in some other way. 5. Distention of the sheath alone was not sufficient to produce papillitis, but might intensify it when in existence. The diagnosis of the cause of the papillitis would depend largely upon the presence or absence of disease in other organs known sometimes to be accompanied by the ocular inflammation.

The value of papillitis as indicating cerebral tumor was very great; it might be the only diagnostic sign of organic central disease. Its subsidence might be regarded in most instances as indicating a retrogression of the growth. It was frequently present in hydatid cyst of the brain. In intra-cranial aneurism it was probably due to descending inflammation from the inflammatory process around the aneurism. In meningitis of the base, papillitis might occur from propagation along the nerve. It was rare in meningitis confined to the convexity. It sometimes occurred in syphilitic meningitis at the base, traumatic meningitis, disease of the cranial bones at the base, etc. When papillitis and glycosuria existed in the same patient, it should be remembered that both might be due to organic cerebral disease. The author then mentioned the other causes of papillitis not of a cerebral nature, and demonstrated the appearance of the disk on the screen.

Orbital Neuritis, including Alcoholic and Tobacco Amblyopia.—DR. HERMAN KNAPP continued the discussion with a paper on this subject. He said that the singular cases in which people noticed a haze, or a blur, or perfect darkness in the centre of vision, known under the name central amblyopia, as well as those cases in which persons lost their sight for one or two days without exhibiting symptoms of any ocular or general disease to account for it, were now known to be due to inflammation in the orbital part of the optic nerve, a retro-bulbar neuritis. It might be idiopathic, or due to alcoholism, to the use of tobacco, to syphilis, etc. It had an acute and a chronic form. The symptoms of the acute form were—headache in various degrees; orbital pain, increased by movements of the eye and pressure; impairment of sight in all degrees. It might begin without any warning, advance rapidly, leading, in exceptional cases, in a day or two, to total blindness of both eyes. Further symptoms were

central scotoma for color and form; general diminution of color perception; moderate redness and serious effusion of the optic disk and adjacent retina. This condition might be followed by ischæmia, or the latter might be noticed from the beginning. It was due to compression of the retinal vessels, the termination revealed one of three ophthalmoscopic pictures—one, the normal condition; two, partial atrophy of the optic nerves; three, total atrophy of the optic nerves.

Etiology.—Exposure; overwork; acute infectious diseases, for instance, measles, diphtheria; rheumatism; alcohol; nicotine; opium; lead poisoning, etc.; suppression of the menses; no assignable cause. The prognosis was doubtful. There might be complete recovery, or partial recovery, or complete loss of sight; sometimes there was one or several islets in the visual field.

The treatment consisted in rest, diaphoretics, salicylate of soda, mercury, iodide of potassium, all of which he thought were of very little avail. He cited a case in which there was no known cause for the total blindness present by the second day after the commencement of headache and difficulty with vision. Dr. Knapp examined his eyes on the second day, when there was no response to light; there was some congestive swelling of the disk. The man was now forty years of age, perfectly well, but blind, except in one islet through which he could count three fingers a distance of fifteen feet.

In speaking of alcoholic and tobacco amblyopia, he said there was diminution in sight in both eyes, coming on gradually, yet with acute aggravation; dim lines; patients saw better in the dusk; diminished perception for color and form, varying according to ring or central scotoma. According to the stage of the disease, one saw with the ophthalmoscope a fairly normal condition or slight congestion. It was almost exclusively in males. The prognosis was good in the first stage where no atrophy of the optic disk was present; it rarely ended in complete blindness. The atrophy in the optic nerve was usually triangular, and might remain after sight had again become normal. In treatment he insisted on total abstinence from alcohol and tobacco. Among remedies were strychnia, iodide of potash, Turkish baths, mountain or sea air.

The lesion was one of retro-bulbar neuritis in which there was a wasting of nerve-fibres, an augmentation of nuclei and hypertrophy of connective tissue. In other words, alcohol produced here an interstitial sclerosis just as it produced a sclerosis of the liver. The degenerated spot, which at first usually had the form of a triangle, might go on and become general, but usually some of the nerve-fibres escaped destruction, which accounted for islets in the visual field. Two years ago he had seen this triangular sector well marked in one eye of a healthy and absolutely sober girl, sixteen or seventeen years of age. On further investigation he found in the same eye a coloboma of the macula lutea. This was a congenital defect, and had been seen since.

In closing he said that retro-bulbar neuritis presented an example of peripheral neuritis of great importance, the nature of which had been correctly foretold by clinical analysis, and proven in a most gratifying manner by the pathologist. The subject of the paper was illustrated by lantern slides and the microscope.

Dr. H. D. Noyes opened the discussion, and said that orbital neuritus, especially that form known as alcohol or tobacco amblyopia, had been placed on positive ground by the investigations of Utoff. The speaker had the last three months chanced to see a number of cases of this sort, and with previous observations he had satisfied himself that the cause might be either alcohol or tobacco, and that it was not necessary for the two habits to be commingled. It was formerly supposed that alcohol, and not tobacco, could produce it; but he thought it had been demonstrated that tobacco alone was quite competent to bring it about. In tobacco poisoning he had satisfied himself that in addition to the impairment of the circulation and weakness of the heart there were also ocular symptoms, including impairment of the function of accommodation, impaired control of the ocular muscles, as well as the affection of the optic nerve. It was not at all rare in the earlier period of the tobacco trouble to have persons present themselves with very little impairment of vision so far as testing by loss was concerned, while deficiency made itself known in blindness for color in the macula lutea.

Appearance of the Optic Nerve not always a Reliable Sign.—Dr. Noyes could not place entire reliance on the appearance of the optic nerve in making a diagnosis. While he fully realized that in a considerable percentage of cases the temporo-inferior quadrant of the disk showed a change, nevertheless he had seen some cases in which it was not a recognizable symptom. Moreover, it was not rare to see this pale appearance in persons in whom there were no toxic effects whatever. Then, again, the lesion did not always present itself in the form of a circumscribed quadrant atrophy, but as a pronounced general atrophy of tissue.

Dr. Noyes referred to cases of injury to the head, in which, although there was no serious injury to the brain, yet blindness followed, resulting, he thought, from an optic neuritis which had its origin in a fissure in the orbital roof.

Dr. David Webster mentioned a case which he thought might be accounted for on the explanation last given by Dr. Noyes, namely, blindness following an injury to the head in which no cerebral trouble was present, and nothing in the appearance of the eye to account for the total blindness. The veins and arteries were normal, and the irides responded perfectly to light. He thought there was perhaps fracture of the roof of the orbit with a lesion of the optic nerve which had not yet become apparent.

Total Abstinence from Tobacco Necessary.—Dr. J. A. Andrews related the case of a man, forty-six years of age, who had tobacco amblyopia, which grew worse in spite of the fact that he reduced his daily quantity of tobacco markedly. Finally he was led to give up tobacco altogether, and in the course of six months the optic nerve cleared up entirely and his vision became normal. This same patient came to his office two years subsequently with the statement that on rising that morning he had queer feelings, but no pain in the head nor body; he simply felt strange, and his sight was not good when he looked in a certain direction. Nothing was visible in the eye to account for the defect in sight, yet there was lateral heteronymous hemianopsia. The supposition was that it was due to cerebral hemorrhage, and the man was advised to go to bed, but instead he went down town to business and next morning was found dead in his bed. No post-mortem. There had probably been cerebral hemorrhage.

Dr. Weeks thought retro-bulbar neuritis could be placed on a more general basis than had been done this evening. It was an interstitial neuritis, and might be caused, he thought, by any condition which would produce a neuritis in other nerves of the body. Alcohol was the most common recognizable cause, but diphtheria, gout, rheumatism, etc., might produce it.

Tobacco and Organic Lesions of the Heart.—The President thought that when tobacco-poisoning reached a point where it produced disturbance of the heart there was something more than functional disturbance; there was a change either in the connective tissue or of the muscular fibres of the heart. Such hearts did not bear ether nor cocaine. He impressed the fact that the heart condition was not functional; it was organic.

A Different Opinion.—Dr. A. Jacobi having elicited from the President the opinion that in such cases there was never, as far as his observation had gone, entire recovery from the heart trouble, said that he could not agree with him. He knew persons who had had functional disturbance of the heart from tobacco-poisoning recover entirely after the use of tobacco had been discon-

tinued. That was a hope which he thought we should hold out to our patients, unless it could be shown that the lesion causing the disturbance was of a nature which did not admit of entire recovery.

The President thought Dr. Jacobi had in mind cases of disturbance of the stomach from use of tobacco, which caused reflex irritability of the heart.

Dr. Jacobi remarked that the President seemed to know his mistakes better than he knew them himself. He did not believe that he had made a mistake, although he thought there was room for diversity of opinion. He would be very sorry to have patients get the idea that their condition was an organic change in the heart which could not be remedied.

Dr. Andrews mentioned a case in which the man was obliged, twenty-five years ago, to give up tobacco on account of disturbance of the heart, and he remained well to-day at seventy-six.

Is there a Tobacco Amblyopia?—Dr. E. V. Agramonte said the condition of the optic nerve shown on the lantern slides was a hyperplasia of the connective tissue. He would ask whether any practitioner present had seen a connective-tissue hyperplasia in any other organ of the body produced by tobacco. Besides, in Havana, where they used a great amount of tobacco, there were comparatively few cases of amblyopia, fewer than in New York. In the cases seen there, the cause had been recognized as alcohol, not as tobacco. It was known, too, that alcohol would produce sclerosis in other parts of the body, and naturally one would expect that it might produce it in the optic nerve. As to the heart, he knew of no case in which it had been demonstrated post-mortem that tobacco had produced hyperplasia of the connective tissue in this organ. He himself was not a smoker, yet for two years, while in the dissecting room, he smoked and suffered from so-called functional disease of the heart in a marked degree, and during that time had had occasion to undergo ether narcosis, and the doctors said he took the ether well. As soon as he quit tobacco he ceased to have heart symptoms. Then it was known that persons would admit the use of tobacco and deny the use of alcohol, which might lead one to suppose that the amblyopia was due to the use of the former, when in fact it was due to the secret use of the latter.

Dr. D. B. St. John Roosa took the view of Dr. Agramonte, which was that held by him some years ago. That is, he was an agnostic with regard to tobacco amblyopia. It had not been proven.

Dr. Knapp, in replying to Dr. Roosa, said it was not alone a question of the use of tobacco, but of the kind of tobacco, or the nature of the poison in the tobacco, which might not be the same in all kinds. As bearing on the heart affection, he said organic changes might exist, as seen in the optic nerve, yet function be restored.

The general subject will be discussed further at the first meeting of the Academy in February, at which Dr. Noyes will read a paper on hemianopsia.

The first Thursday in January will fall on New Year's Day, and after some discussion whether the meeting for the election of officers, which should fall on that day, could be postponed, it was finally decided that two or three could meet on the first, and adjourn business until the eighth, on which day the election will take place.

The Medical Examiners Bill.—Dr. A. Jacobi: I rise, Mr. President, to make a motion, with a few preliminary remarks. The New York Academy of Medicine is a power acknowledged by the profession, the public, and the authorities. It has attained this because its influence is not what is generally called political. What has given it its high position is indeed nothing but the fact that it never forsook the object for which it was founded, namely, the cultivation of medical science and art, and the elevation of the standard of medical education, and of the profession.

After nearly twenty year's efforts, and the outlay of considerable sums of money, the profession finally succeeded, nearly two years ago, in securing a bill providing for a State Examiners Board. Unfortunately, as is well known, three boards have been established instead of one. But the principle has been established that the community is entitled to ascertain by a State examination whether a graduate of a college shall be permitted to practise, and that the ranks of the profession shall be swollen only by those who are amply fit. The second bill which has been secured by the efforts of the profession refers to a preliminary education No person, in future, is permitted to obtain a medical diploma, unless he or she can bring proof of having attained to a certain degree of intellectual culture.

As there is danger of repetition of attempts to repeal these beneficent laws, such attempts having been made last winter, or to so change them that they may be still less effective, I move as follows:

The New York Academy of Medicine considers the law establishing a State Board of Medical Examiners, and the law exacting a preliminary education from those who intend to obtain a medical diploma, as stages of progressive development. It deplores the insufficiency of these laws, but rejoices at the recognition by the Legislature of the principles on which they are based. It feels that, as they are, they deserve being tested, and ought not to be changed, amended, or repealed before their efficacy or inefficacy will have been proven by the experience of years.

Dr. D. B. St. John Roosa seconded the motion, with some earnest remarks, and said he feared the profession would get something worse than the present bill, should a change be made before at least a year's trial.

The motion was carried, and the secretary was instructed to send a copy to the State authorities.

Correspondence.

A VITAL QUESTION FOR THE WORKING PHYSICIAN.

To the Editor of the Medical Record.

Sir: That charity is wholesome to the soul no physician, having himself so often enjoyed the remembrance of a kindly act, will deny. As with liberty, so with charity; when not well bestowed it becomes a curse not only to the recipient, but also to the donor; sweet charity is a balm to the worthy, to the unworthy it is an incentive to degradation. To-day, in this city, charity, as represented by our free dispensaries, is working a vast amount of harm—demoralizing men and women, making of them thieves, for they who can afford to pay a physician and who receive free treatment at dispensaries virtually rob the poor, while they deliberately lie so as to obtain such care. The physician, as every other citizen, is interested in the welfare of society, and by his calling is bound to elevate the *morale* of the community. Do we do so? No, we daily allure to our hospitals, dispensaries, and college clinics patients who can well afford to pay for home treatment at the hands of physicians who have given the best years of life to study, and who should be allowed to make an honest living in an honorable profession.

It seems that the medical profession has lost its ancient reputation for honor, the only cry now is "Catch a patient if you can," no matter what other brother practitioner may have been faithfully and skilfully treating him; steal every case that may come under your attention; stab your confrère, it may not be by harsh words, but by a more infernal plan, honeyed praises, with a saving clause injected, viz.: I can do better. On all sides such a state of affairs exists, and without seeming pessimistic we must admit it as we every day see it. The honest hod-carrier will not take a job out of the hands of his fellow-worker—else he becomes a scab—nay, he goes further, he will strike to protect his kind. What a lesson given by the humble laborer to the learned professional gentleman!

We find more honor among the toilers than among physicians.

This system has its origin and extension in our free medical charities of the present day; it is not due to a healthy and laudable competition, and some means must be found to arrest the growing evil. In one institution, known to the writer, between five and six hundred patients, daily, receive treatment, and not one-half the number deserving. Frequently the young "Dispensary Doctor" slips his card to the patient, with the suggestion, "You had better call at my office," and then begins a time when the tempered wind to the shorn lamb becomes a cyclone, which sweeps the dollars out of the innocent lamb's wool. At the same time a neighboring physician, well read, conscientious in his profession, armed with hard-earned skill, and holding a diploma granted, perhaps, by the Institution which takes the bread from his family, sits in his office and literally starves to death.

A great responsibility lies with the medical colleges which take the money of the graduate and then raise up institutions to nullify the value of their certificate to practise. It is time that the Faculties of the different colleges come together and devise some plan to stamp out this wholesale system of robbery and deceit. Here, naturally, comes the question, How can it be done? How can we separate the worthy from the unworthy? Granted that the problem is a difficult one to solve. However, I will humbly submit a plan which, if honestly carried out, will, I believe, help carry us over the bridge. My suggestion is: That each hospital and dispensary, print cards stating specialties, if any, hours of service, names of attending physicians, etc., and such cards to be distributed to the members of the profession in the city, requesting that the physician vouch for the applicant for free treatment as being worthy, which voucher will certainly not be withheld by any reputable physician if the case be a deserving one. This may, for a time, bother the physicians and cause them some trouble; but the benefit of weeding out the drones will eventually bring dollars into the treasury, for while the deserving poor will not suffer, the frauds will have to take a back seat or pay what is just and right. Such a plan, if adopted, would undoubtedly help to replace the medical profession on the old standing, and bring to it a respect now lacking. Another point that might be canvassed: Is it right for a rich corporation to give treatment for a monthly nominal sum? The writer has a patient who paid $1 monthly for treatment in an institution rich in money and lands, while he is fully able to pay $2 a visit.

Private dispensaries also require the attention of medical societies—such institutions are under no restriction and amenable to no law. A dose of legislation would be in order, either purgative or alterative.

M. A. C.

[The only trouble is that it takes two to make a bargain, and college clinics and dispensaries are in need of all the clinical material they can obtain by fair means or otherwise.—Ed.].

A COMPLAINT AGAINST THE UNDERTAKER.

To The Editor of the Medical Record.

Sir: I desire to make a complaint. It is this. After attending patients through their last illness I am called upon to sign a certificate of death. This is sent to the Board of Health. Many times I also make out and sign an insurance certificate. I am told by some that my bill will be paid when the insurance policy is honored by the company. I believe it has been said that "hell is paved with good intentions." Well, to come to the point, that is the last I ever hear of my bill, and it is not paid. I have been "worked" so often by this scheme that I made up my mind to try another mode of action. I refuse to sign the insurance certificate, hoping to be paid. The generous gentleman to whom the burying process is entrusted obligingly helps my debtor out of the small trap set for him by me, and he, the undertaker, obtains a transcript from the Board of Health, which, I am informed, is accepted as a proof of death by the companies, and I am "left" again. The undertaker gets his fee because he goes to the office of the company with the person to whom the money is left by the deceased, and, as a rule, cashes the insurance company's check, helping himself and giving in exchange the change. Considering what a good friend to the undertaker the doctor is said to be, I think that it is very ungrateful conduct on the part of that dignitary.

Is there no relief for doctors?

Is it fair that a transcript be issued when the doctor's bill most certainly would be paid (cheerfully) if that transcript were not given? I think the editor knows how hard it is for a young doctor to make both ends meet, and that when he can obtain pay for his services that it is mean to do him out of it.

I am most sincere in appealing to you in this matter, and I feel certain you will give it your kind consideration.

Yours sincerely,

Philip F. O'Hanlon, M.D.

[Moral: Keep all the possible business out of the undertaker's hands.—Ed.]

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 4, 1891, to January 10, 1891.

Sutherland, Charles, Colonel and Surgeon, to be Surgeon-General, with the rank of Brigadier-General, December 23, 1890. Vice Baxter, deceased. By direction of the Secretary of War, he will, as soon as practicable, repair to Washington, and assume the duties of his office. Par. 9, S. O. 2, A. G. O., Washington, D. C., January 3, 1891.

Official List of Changes in the Medical Corps of the United States Navy for the week ending January 10, 1891.

Ruth, M. L., Surgeon. Ordered to the Newark, February 2, 1891.

Rush, W. H., Passed Assistant Surgeon. Detached from the Saratoga, and ordered to the Newark, February 2, 1891.

Asheridge, Richard, Passed Assistant Surgeon. Ordered to the Saratoga.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 10, 1891.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	8	3
Scarlet fever	153	16
Cerebro spinal meningitis	3	5
Measles	398	15
Diphtheria	101	14
Small-pox	0	0
Varicella	9	0
Pertussis	4	8
Croup	1	0

Patents for Dental Work.—At a meeting of the Central Dental Association, held last fall in Newark, Dr. W. F. Rehfuss, of Philadelphia, read a paper entitled, "The

Jurisprudence of Dental Patents, and the Legal Interpretation of Claims of Patents granted for Artificial Crowns and Bridge Work." The author said the great number of patents threatened the welfare of dentistry as a liberal profession, and would endanger its progress. The subject of patent methods, he said, was peculiar to dentistry of all the healing arts, and dentistry was of necessity forced to harbor and submit to such degrading systems. More than two hundred patents had been granted, he said, for modes of operating, and the whole number would exceed one thousand if patents for instruments were included. The author contended that dental operations should not be patented, but that instruments to perform the operations were legitimately patentable.

Reunion of Severed Parts.—The two following cases are interesting as showing how much can be accomplished by skilful conservatism in surgery. The first case is one reported by Mr. George Gordon in the *British Medical Journal*. The patient was a healthy, well nourished girl of six, who had had the fleshy portion of the middle finger stripped completely off the two distal phalanges. While playing with some other children in a wood-yard a plank of timber had fallen on her hand: she immediately withdrew the hand, with the above-mentioned result. The intention was to amputate the finger, but the mother produced the missing member, which had been found wedged in between the planks, and this led the writer to resolve to give the limb a chance, so he carefully washed the finger, which had by this time been laid aside for fully an hour. It was burst open along its palmar aspect to within a short distance of the tip, so the operator slipped it over the denuded bone, as one would do the finger of a glove. The lacerated edges were brought together by eight silk sutures, and a carbolic dressing was applied, the whole hand being warmly dressed to maintain the temperature. It was seen again twenty-four hours afterward, but the process of repair did not seem encouraging. Two days afterward it was seen again, but now vascular granulations from the lacerated stump seemed to shoot into the apparently dead finger, and on subsequent visits an increased temperature with decided vitality manifested itself. Some time afterward the patient again injured the tip of the same finger, and it had to be removed, but the remaining portion did well, becoming firmly united to the bone. The second case is one reported in August last by Dr. J. M. Kelley in the *Times and Register*. He writes as follows: "On July 1st I was called to the Kincaid Cotton Mills, Griffin, Ga., and upon my arrival I found a young man bleeding from the nasal locality. After examination, I discovered that all the soft part of his nose was gone, except about one-third of the left wing and a thin anterior flap of the nasal septum, which was lying down upon the upper lip, still attached at its lower end. I was informed that it was cut off by a belt which had slipped off of its pulley while the machinery was in motion. I ordered the missing member brought to me; after a short search it was found. I washed it and warmed it thoroughly in warm water lightly impregnated with bichloride of mercury, placed it in its proper position, raised the anterior flap, and stitched all around with surgeon's silk. I then introduced into each nostril two large drainage-tubes, compressed and confined the parts firmly with several strips of isinglass plaster. Over the entire nose I placed a piece of oiled silk. During the first twelve hours I kept up continual warmth by laying across the nose a flannel doubled three or four times, saturated with a warm solution of bichloride of mercury. I also injected frequently this warm solution into the nostrils. On the second day nothing was done except to keep a dry flannel across the nose. On the third day I removed the drainage-tubes, washed out each nostril with warm bichloride solution, dried the parts, and placed the tubes back as before. I repeated this almost daily until the tenth day, when I removed all of the dressing and found the nose alive and united except a small triangular notch in the right wing which was so badly bruised as to cause it to die. The time the nose remained off was about one hour."

A Simple Pneumatic Method of Removing Foreign Substances from the Nasal Cavity of Children.—Dr. T. J. Slaton, of Greenville, Ky., describes this method as follows: "The operator places a thin cloth over the child's mouth, applies his finger to the nostril not containing the substance, pressing sufficiently to close the lumen, and then puts his mouth to the child's and gives two or three strong puffs. The substance will fly out nine times out of ten. I have blown them ten feet out, often. I have used this method for the last ten years with but one failure; in that case I failed but forced the substance so near the anterior nasal opening that I had no trouble in removing it with forceps."

How to Give Chloralamid.—Much depends upon the proper administration of the new hypnotic, choralamid, to obtain the full effect and satisfactory and beneficial results. The dose is from 15 to 60 grains, with an average dose of 30 grains. Chloralamid is soluble in about 20 parts of cold water, and in 1½ part of alcohol. An additional caution is necessary: Never dissolve or dispense chloralamid in hot water or warm solutions, as the heated preparation decomposes. The best modes of administration are: 1. In a tablespoonful of whiskey or brandy. 2. In properly proportioned solutions with wine, spirits, or spirituous compounds. 3. In a small cup of cold water or cold tea. 4. In powder form, in wafers or cachets washed down with cold water.

The Ideal Malthusian Marriage.—It is stated by Dr. Keppler, of Venice, that spaying for salpingitis and other inflammatory affections in young women does not produce any diminution of the sexual appetite, but that, notwithstanding certain changes in the genital organs that remain, these women can marry and live happily with their husbands. Indeed, he suggests that marriage with a spayed woman is the ideal of a Malthusian marriage, as a happy married life without conception and without any danger to health can be obtained. Very different is the result of spaying in middle-aged women with fibromata, for it entirely destroys all traces of sexual instincts.—*The Hospital Gazette.*

Excision of the Hip.—To obtain primary union in six out of seven cases of excision of the hip for tubercular hip joint disease may fairly be regarded as a very good record. This record was presented to the Medical and Chirurgical Society at a recent meeting by Mr. Arthur Barker. In all the cases operated on, advanced disease was present together with abscess, prolonged rest having failed to prevent the development of the latter. By means of hot water flushing combined with gouging (in the manner devised by Mr. Barker) the tuberculous material was evacuated so thoroughly that it became safe to close the wound and look for primary union "a sound cicatricial tissue taking the place of the diseased area, and all open sinuses being prevented." The only case out of the seven which did not do well was one in which the conditions under which Mr. Barker recommended this procedure had been violated. It served, therefore, to illustrate the limits which might be set to the method. It was that of an exceedingly debilitated and neglected boy, aged seven, in whom the right hip-joint was palpably destroyed by advanced disease and converted into a large thin-walled abscess, the skin over which was thin and red and evidently about to give way. The contents were mostly inflammatory pus, the part having been aspirated some time previously—probably with a non-sterilized needle, the track of which was observed to suppurate later on. This joint was treated by the method in question, though without much hope that it could be got to heal by first intention. It did not do so, and hot

fomentations and drainage had to be resorted to. The boy, however, steadily improved and ultimately left University College Hospital greatly increased in weight, and with only a very small sinus remaining in the joint. After narrating the remaining cases Mr. Barker said he did not advocate his method of procedure as one to supersede local and general treatment, but rather as a means of treating tuberculous hips where other means had failed and abscesses were forming and ready to burst.

Eighty-fifth Annual Meeting of the Medical Society of the State of New York, Tuesday, Wednesday and Thursday, February 3d, 4th, and 5th, in the City Hall, Albany. *Provisional Programme:* Tuesday, Morning Session, 9.30 A.M.: President's Inaugural Address, Appointment of Committees, Executive Business. Papers: "Railroad Surgery," by Clinton B. Herrick, M.D., of Troy; "A Report of Cases of Injury to the Knee-Joint, with Remarks," by Henry Flood, M.D., of Elmira; "The Management of Sinuses in Chronic Bone and Joint Diseases," by V. P. Gibney, M.D., of New York; "Necrosis of the Ribs, Complicating Pott's Disease," by Louis A. Weigel, M.D., of Rochester; "Brief Notes on Gastrostomy, with Report of a Successful Case," by Charles A. Powers, M.D., of New York; "The Action of Trypsin, Pancreatin, and Pepsin upon Sloughs, Coagula, and Muco-pus," by Robert T. Morris, M.D., of New York; "Operative Procedures in Acute General Suppurative Peritonitis," by W. E. B. Davis, M.D., of Birmingham, Ala.; "The Progress of Cystoscopy in the Last Three Years," by Willy Meyer, M.D., of New York; "A Plea for Rapid Dilatation, Holt's Operation, in the Treatment of Urethral Stricture," by F. R. Sturgis, M.D., of New York; "A Case of Imperforate Anus of Eight Weeks' Standing. Operation and Recovery," by William Hailes, Jr., M.D., of Albany. Afternoon Session, 2.30 P.M.: "Diagnostic Significance of the State of the Pupils," by E. C. Spitzka, M.D., of New York; "Three Diagnostic Symptoms of Melancholia. Second Communication," by Landon Carter Gray, M.D., of New York; "Hysterical Manifestations Due to Alcoholism," by H. C. Coe, M.D., of New York; "Cases of Traumatic Hysteria," by Henry Hun, M.D., of Albany; "Insomnia and its Treatment," by E. N. Brush, M.D., of Philadelphia; "The Cause of Asthenopia," by D. B. St. John Roosa, M.D., of New York; "The Treatment of Detachment of the Retina," by David Webster, M.D., of New York; "On the Use of Platinum Instruments in the Extraction of Cataract and in Other Operations upon the Eye," by E. Gruening, M.D., of New York; "Contagion from Roller Towels," by Lucien Howe, M.D., of Buffalo; "One Thousand Cases of Ocular Headache and the Different States of Refraction Connected Therewith," by W. F. Mittendorf, M.D., of New York; "Catarrh and its Cure," by O. B. Douglas, M.D., of New York; "On the Causes of Eczema," by L. Duncan Bulkley, of New York; "Some Points in the Pathogenesis of Aural Vertigo," by Oren D. Pomeroy, M.D., of New York; "Certain Hygienic Measures in the Treatment of Catarrhal Affections of the Upper Air Passages," by F. H. Bosworth, M.D., of New York; "A Contribution to the Surgical Treatment of Jacksonian Epilepsy. Excision of the Arm Centre," by Edward B. Angell, M.D., of Rochester. Evening Session, 7.30 P.M.: Discussion on "Appendicitis." "The Pathology of Appendicitis," by Herman Mynter, M.D., of Buffalo, and Arpad G. Gerster, M.D., of New York; "The Indications for Early Laparotomy in Appendicitis," by Charles McBurney, M.D., of New York, and William W. Keen, M.D., of Philadelphia; "The Technique of Operative Interference in Appendicitis," by Lewis A. Stimson, M.D., of New York, and George Ryerson Fowler, M.D., of Brooklyn; "The Propriety of and the Indications for the Resection of the Appendix Vermiformis During the Quiescent Stage of Chronic Relapsing Appendicitis," by Joseph Price, M.D., of Philadelphia, and Robert F. Weir, M.D., of New York; "The Relation of the Physician and the Surgeon in the Care of Cases of Appendicitis," by Albert Vander Veer, M.D., of Albany.

Wednesday, Morning Session, 9.30 A.M.: Discussion "On Pelvic Inflammation in Women; its Pathology and its Palliative, Conservative, and Radical Treatment." "Introduction," by Andrew F. Currier, M.D., of New York; "Pathology," by A. J. C. Skene, M.D., of Brooklyn, and W. Gill Wylie, M.D., of New York; "Palliative Treatment," by C. C. Lee, M.D., of New York; "Conservative Treatment," by W. M. Polk, M.D., of New York; "Radical Treatment,' by Joseph Price, M.D., of Philadelphia, and L. S. McMurtry, M.D., of Louisville, Ky. These papers will be discussed by Dr. Thomas Addis Emmet, of New York, Dr. Franklin Townsend, of Albany, and others. Papers: "The Treatment of Posterior Displacements by the Utero-Vaginal Ligature," by H. J. Boldt, M.D., of New York; "Minor Gynecological Surgery," by Maurice J. Lewi, M.D., of Albany; "The Treatment of Injuries to the Floor of the Vagina," by Horace Tracy Hanks, M.D., of New York; "An Inquiry into our Present Knowledge of the Progress of Myomatous Tumors after (*a*) The Use of the Electric Current; (*b*) Removal of Ovaries and Tubes; (*c*) The Old Method of Treatment by Rest, Intrauterine Applications and Ergot," by James F. Mundé M.D., of New York; "Surgical Treatment of Ectopic Gestation," by Charles A. L. Reed, M.D., of Cincinnati, O.; "Some of the Results of Defective Sanitary Arrangements in the Puerperal State," by James P. Boyd, M.D., of Albany; "The Management of Tedious Labor," by Egbert H. Grandin, M.D., of New York; "A Report of Four Cases of Cancer of the Clitoris where Clitoridectomy was Performed," by Franklin Townsend, Jr., M.D., of Albany; "The Emotional Element, the Puerperal Period," by Adam H. Wright, M.D., of Toronto. Afternoon Session, 2.30 P.M.: Discussion on "Pulmonary Tuberculosis:" "History," by H. R. Hopkins, M.D., of Buffalo; "Etiology and Pathology," by Heneage Gibbes, M.D., of Ann Arbor, Mich.; "Diagnosis and Prognosis," by A. L. Loomis, M.D., of New York; "Manifestation in Upper Air Tract and Special Treatment Thereof," by John O. Roe, M.D., of Rochester; "Treatment, including Prophylaxis, as related to Climate," by Samuel B. Ward, M.D., of Albany; "Treatment as related to Therapeutics, including Koch's Method," by E. L. Shurley, M.D., of Detroit. Papers: "Koch's Lymph and Tuberculosis," by A. Jacobi, M.D., of New York; "Therapeutic Notes on Acute Respiratory Diseases," by A. Jacobi, M.D., New York; "Lobar Pneumonia, with the Production of Connective Tissue in the Air Spaces," by Francis Delafield, M.D., of New York; "The Treatment of Gall Stones," by William Watkyns Seymour, M.D., of Troy; "Treatment of Itching," by Edward B. Bronson, M.D., of New York; "Croupous Rhinitis," by Frank H. Potter, M.D., of Buffalo; "The Correction of Angular Deformities of the Nose, by a Subcutaneous Operation," by John O. Roe, M.D., of Rochester; "A Case of Pemphigus," by H. R. Hopkins, M.D., of Buffalo; "The Treatment of Pigmentary and Vascular Nævi," by George Henry Fox, M.D., of New York. Anniversary Address, by the President, at 8 P.M., in the Assembly Chamber; Annual dinner of the society, at 9.30 P.M., at the Delavan House.

Thursday, Morning Session, 9.30 A.M.: Executive business. Papers: "The Relation of Physicians to Boards of Health," by Lewis Balch, M.D., of Albany; "The Necessity of an Amendment in the Laws Governing Medical Evidence in Malpractice Suits," by R. J. Wilding, M.D, of Malone; "The Present Status of the Proposed Law to Regulate the Practice of Embalming Human Dead Bodies," by A. Walter Suiter, M.D., of Herkimer; "The Unrestricted Evil of Prostitution," by Andrew F. Currier, M.D., of New York; "A Case of

Scarlet Fever with Vesicular Eruption," by F. C. Curtis, M.D., of Albany; "Intestinal Obstruction, Report of Cases," by J. H. Glass, M.D., of Utica; Subject to be announced, by William S. Ely, M.D., of Rochester; Subject to be announced, by Clarence C. Rice, M.D., of New York.

The Zymotic Diseases in New York: Their Prevalence, Mortality, and Sanitary Management.—The Tenth Annual Report of the State Board of Health of New York, for the years 1888 and 1889, has recently been issued. It contains an immense amount of interesting and valuable matter. The mortality statistics and the very excellent deductions drawn from them by Dr. F. C. Curtis deserve wide reading by physicians. Following is an abstract of his remarks on the zymotic diseases:

Typhus Fever.—Seven deaths in 1888, all in New York and Brooklyn. None in 1889, for the first year in the history of the Board. During the past five years 80 deaths have been reported.

Cerebro-spinal Fever.—Four hundred and ninety deaths in 1888, and 596 in 1889. Geographically it is pretty generally distributed throughout the State, but notably adheres to certain localities such as New York, Buffalo, Troy, and Gouverneur. It is a remarkable fact that New York reports deaths from this disease every month in the year, while none is reported from Brooklyn. In fact, during the seven years that records have been kept, there has been only one death from cerebro-spinal fever in Brooklyn—in May, 1885. As to seasonal distribution, the statistics show that its greatest prevalence is in the spring months, and its least in the summer. No other zymotic disease, however, is so constantly present. The high level of surface- or ground-water is put forth as a possible etiological factor; this is noticeable in St. Lawrence County and along the St. Lawrence River) and it is recommended to try the effect of draining the soil in the especially affected regions.

Malarial Diseases.—There were 842 deaths reported in 1888, or 0.8 per cent. of the zymotic mortality; 742 deaths in 1889, or 0.75 per cent. of the zymotic mortality. The largest proportion of these deaths occur in the fall months and the least in summer.

Typhoid Fever.—There were 1,449 deaths in 1888, or 1.4 per cent. of the total mortality, and 1,571, or 1.5 per cent. in 1889. This is about the usual average. The deaths began to increase in August, continuing to do so in September and October, and then diminishing till January, the first seven months of the year being comparatively free from the disease. There were no noteworthy epidemics of the disease in either 1888 or 1889.

Small-pox.—Until December, 1887, small-pox was comparatively unknown in New York State for years, at least outside of the maritime centres, where, from its exposure from outside, cases may at any time appear. In 1885, in spite of an extensive epidemic in Montreal, there were only 33 deaths in New York State, 28 of which were in New York City. In 1886 there were 39 deaths, all but 2 being in the metropolis. In 1887 there were 175 deaths, 171 of which occurred in New York, Brooklyn, and their immediate vicinity. In December of 1887, however, an epidemic began that extended to various parts of the State and lasted till April, 1889, affecting about fifty localities. There were 12 deaths in December, 1887, and 210 in 1888, the greatest number being in March, April, and May—35, 40, and 42, respectively. In 1889 there were 30 deaths reported, all but 3 being before May. The starting-point was usually traced to the metropolitan centre. It broke out in the Indian reservations in the western part of the State, and threatened to be general; but vaccination and rigid quarantine limited the outbreak to 6 cases, with 4 deaths. The energy of the boards of health in speedily accomplishing the control of this disease is to be commended Another outbreak is not probable in the near future.

Measles.—This disease was less prevalent in 1888 and 1889 than usual, causing about 9.50 per 1,000 of the total mortality. It varies greatly in prevalence and occurs usually in epidemics; although small-pox was unusually prevalent in 1888 it did not cause one-fourth as many deaths as measles.

Whooping-cough.—This is even more variable in prevalence than measles. There were 834 deaths reported in 1885, 1,244 in 1886, 447 in 1887, 902 in 1888, and 1,332 in 1889.

Scarlet Fever.—The report is given in full concerning this disease: "Here we have a disease of much more importance than either of those spoken of. In each 1,000 deaths there were, in 1885, 14.5 from scarlet fever; in 1886 there were 11.7; in 1887 there were 13.2; in 1888 there were 22.8; and in 1889 21.2 deaths per 1,000 total mortality. It is much more prevalent and fatal as a rule in the winter and spring months, both relatively and absolutely. The necessity for quarantine and disinfection ought to be emphasized in scarlatina. If this were done in every case the spread of the disease would be greatly lessened. The same care should be used in regard to it as with small pox, which it resembles more than any other zymotic disease in regard to the vitality and portability of its virus. It is certain to cause a great many more deaths than small-pox ever will, lacking as it does the protective procedure of vaccination, and it is only to be controlled by restriction of the sick and destruction of the virus."

Diphtheria.—This causes the most deaths of all zymotic diseases. In 1885–86–87 it caused 32.35 per cent. of the zymotic mortality; in 1887, 32.20 per cent.; in 1888, 29.30, and in 1889, 27.3. It is a winter disease. It is found in all cities as well as the most retired and rural localities. It seems to have become endemic in the cities. Once established the morbific principle is liable to inhere. Few doubt that it is contagious, but it depends more on its environments than small pox, measles, etc., which appear to thrive in sanitary as well as unsanitary localities. There is a susceptibility of locality as well as a personal susceptibility in diphtheria. There is a manifest bearing in the saturation of the soil or high level of ground-water. Village sites with damp, wet cellars, especially those imperfectly ventilated and having mould on the walls, are apt to have diphtheria. The *rationale* perhaps is that those living over such cellars are prone to sore-throat and to develop personal susceptibility, but there is also the upward draught carrying moisture and decomposing matter. There is a relation between filth and dampness and diphtheria. The disease does not linger in clean, well-ventilated, dry, airy places. It is contracted in two ways, by direct personal contact or by inhaling air emanating from a spot which furnishes conditions favorable to the development and culture of its disease-germs, which at some previous time have become planted there. Bad sanitary conditions make the culture-beds and explain repeated outbreaks of the disease in the same house. In many instances it is possible to rectify the conditions on which the perpetuation of the germ depends by soil drainages, avoidance of its pollution, cleanliness, and ventilation. That the disease can originate under these unsanitary conditions, without the importation of the germ, is not probable. The germs are remarkably long lived, cling tenaciously to articles on which they are deposited, and can thus travel long distances. The sanitary inspector meets the disease in two conditions—an outbreak due to direct personal exposure to the disease or germ, imported into a locality previously free from it; secondly, he finds it prevailing in a village, where there is a recurrence of the cases, one or more at a time, at intervals of some weeks perhaps, but constantly recurring for an indefinite period. Stop the further spread of the disease by quarantine. Cut off all unnecessary communication between the sick and well, and destroy all generated infectious material. In the second condition, however, more is necessary. The unsanitary foci where the germs are propagating must be found and destroyed.

Reviews and Notices of Books.

The Science and Art of Obstetrics. By Theophilus Parvin, M.D., LL.D., Professor of Obstetrics and Diseases of Women and Children, Jefferson Medical College, Philadelphia. Second Edition. 8vo, pp. 704. Philadelphia: Lea Brothers & Co. 1890.

The second edition of this work is fully up to the present state of advancement of the obstetric art. The author has succeeded exceedingly well in incorporating new matter without apparently increasing the size of his work, or interfering with the smoothness and grace of its literary construction. He is very felicitous in his descriptions of conditions, and proves himself in this respect a scholar and a master. Rarely, in the range of obstetric literature, can be found a work which is so comprehensive and yet compact and practical. In such respect it is essentially a text-book of the first merit. The arrangements of the subjects are stereotyped, but their treatment gives the real value to the work—the individualities of a practical teacher, a skilful obstetrician, a close thinker, and a ripe scholar.

Index Catalogue of the Library of the Surgeon-General's Office, U. S. A. Authors and Subjects. Vol. XI. (Phædronus—Régent.) 4to, pp. 1102. Washington. 1890.

The eleventh volume of the Catalogue of the Library of the Surgeon-General's Office is equal in size and importance to that of its predecessors. It includes 9,539 authors' titles, representing 4,535 volumes and 8,908 pamphlets. It also includes 14,262 subject-titles of separate books and pamphlets, and 38,080 titles of articles in periodicals. Dr. John S. Billings is still very properly the supervising genius of the series.

Medical Diagnosis, with Special Reference to Practical Medicine: A Guide to the Knowledge and Discrimination of Diseases. By J. M. Da Costa, M.D., LL.D., Professor of Practice of Medicine and of Clinical Medicine, Jefferson Medical College, Philadelphia. Seventh edition. 8vo, pp. 995. Philadelphia: J. B. Lippincott Company. 1890.

The seventh edition of this classic work has been thoroughly revised and much new matter has been incorporated, together with numerous woodcuts illustrating "such micro-organisms as have been proved to be of practical significance in diagnosis." For over a quarter of a century this treatise has maintained its leading position in clinical medicine, and is likely to continue its reputation for some time to come. In its particular line it is without a rival.

A System of Oral Surgery: being a Treatise on the Diseases and Surgery of the Mouth, Jaws, Face, Teeth, and Associate Parts. By James E. Garretson, A.M., M.D., D.D.S., President Medico-Chirurgical Hospital, etc., Philadelphia. Fifth Edition. 8vo, pp. 1364. Philadelphia: J. B. Lippincott Company. 1890.

The fifth edition of Professor Garretson's admirable work is enlarged and improved in many ways as compared with former ones. In almost every chapter new matter has been added in order to keep pace with the improvements in oral surgery, so rapid and radical during the past few years. The work for a considerable period has occupied a field of its own, and has vindicated its claim to recognition by the prompt calls for successive editions. At present it is almost encyclopedic as referring to the diseases of the oral cavity. We have here everything, from plugging a dental cavity to extirpation of the jaw. Even the surgery of the neck and nose are placed under contribution. Although this is somewhat beyond the specialty, the surgical as well as the dental reader will pardon the author in view of the admirably exhaustive and practical manner he has treated every subject in the work. Although intended more for dentists than general surgeons, the latter will find much in it that is new and interesting, especially such as refers to the author's personal experience. The application of the surgical engine to operations upon the jaws for removal of tumors, is a new departure long and creditably associated with the author's name, and the profession at large cannot be too grateful for his adaptation to some of the most difficult surgical procedures. It is most profusely illustrated.

A Text-book of Practical Therapeutics, with Especial Reference to the Application of Remedial Measures to Disease, and their Employment upon a Rational Basis. By Hobart Amory Hare, M.D. (Univ. Pa.), B.Sc., Clinical Professor of Diseases of Children, and Demonstrator of Therapeutics in University of Pennsylvania, etc. 8vo, pp. 632. Philadelphia: Lea Brothers & Co. 1890.

"The object of this book," says the author, "is to provide the physician or undergraduate student of medicine with a reliable guide in the study of therapeutics, or the application of remedial measures for the cure of disease." In fulfilling this object the author has endeavored, very successfully we believe, to so arrange the departments of his subject as to give them a thoroughly practical and scientific bearing. His aim has been to demonstrate when and how the different remedies may be applied to the commoner diseases in their different stages. Part I., on general therapeutical considerations, is brief and to the point regarding the action of drugs, dosage, modes of administration, absorption, indications, counter-indications, etc., making a fitting general introduction to the divisions which follow. Part II. discusses the various drugs in alphabetical order, under the subdivision of physical properties, physiological action, their effects upon the different systems, their uses in different diseases, dosages, and poisonous effects. All the newer remedies are included in this list, and the author makes a very laudable endeavor to substitute other than proprietary names for many of the more fashionable ones. Under the present system of complicated chemical nomenclature, the outlook as to good results of such substitution is by no means as promising as we might wish. Part III., under the heading of remedial measures other than drugs, we have noticed acupuncture antiseptics (which is treated quite exhaustively), the remedial effects of cold and heat, counter-irritation, disinfection, and venesection, concluding with diets for the sick. Part IV., which is the most interesting portion of the work from a practical standpoint, is treatment of the commoner diseases by the usual drugs, and lastly follows an alphabetical table of doses. The work is well written, is thoroughly practical, and is a valuable addition to the literature of therapeutics.

A Manual of Modern Surgery: An Exposition of the Accepted Doctrines and Approved Operative Procedures of the Present Time. By John B. Roberts, A.M., M.D., Professor of Surgery in Woman's Medical College of Pennsylvania, etc. 8vo, pp. 800. Philadelphia: Lea Brothers & Co. 1890.

This work is a very comprehensive manual upon general surgery, and will doubtless meet with a favorable reception by the profession. It has a thoroughly practical character, the subjects are treated with rare judgment, its conclusions are in accord with those of the leading practitioners of the art, and its literature is fully up to all the advanced doctrines and methods of practice of the present day. Its general arrangement follows this rule, and the author, in his desire to be concise and practical, is at times almost dogmatic; but this is entirely excusable, considering the admirable manner in which he has thus increased the usefulness of his work.

THE FRANKLINIC INTERRUPTED CURRENT;

OR, MY NEW SYSTEM OF THERAPEUTIC ADMINISTRATION OF STATIC ELECTRICITY.[1]

BY WILLIAM JAMES MORTON, M.D.,

NEW YORK CITY.

THE object of this paper is to lay before the profession more explicitly the writer's new system of treatment of disease by Franklinic or static electricity. The old system by sparks and other forms of the disruptive discharge upon the person is already sufficiently familiar. What I here designate as my new system has developed itself to me gradually during the last ten years. Parts of it I have published, other parts not. Granting and acting upon that moral dictum which forbids the physician from patenting his inventions and discoveries, I may remark in passing, as illustrative of the disadvantages under which

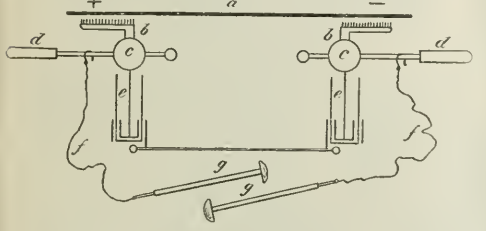

FIG. 1.—Uninterrupted Primary Circuit of a Holtz Machine, with or without Condensers. *a*, Rotating plate; *b*, *b*, collecting combs; *c*, *c*, prime conductors; *d*, *d*, discharging rods; *e*, *e*, Leyden jars; *f*, *f*, conducting cords; *g*, *g*, sponge or other electrodes. Upon grasping the two electrodes and setting the machine in motion no current is felt and no action on nerve and muscle perceived.

he is placed thereby, that some makers of Holtz machines are now generally attaching my inventions to their machines and adopting my methods without the slightest credit, while one even has gone so far as to take out patents for the very things I had published widely. The demands which are daily made upon electro-therapeutics in general and its brilliant extension into the domain of gynecology induces me to now present the facts in their entirety, in order that they may take their share, according to their merits, in the universal progress.

Up to the time of the writer's first apparatus in 1880, and first publication in 1881, concerning "a new induction current in medical electricity,"[2] static electricity had been applied medically by administering a spark, or some modification of it, direct to the person of the patient, or by giving in the same direct manner a single shock from a Leyden jar. From the earliest medical electrifications by the Abbé Nollet, in 1734, onward and successively through the revivals of the practice by Golding Bird, Sir William W. Gull, and Wilks, of Guy's Hospital, London, in 1837, 1851, and 1873; by Schwanda and Clemmens respectively in Austria and Germany; by Vigoroux and Charcot, in Paris in 1879, and by myself in America in 1880, we become familiar with breeze, spray, sparks, and shock, but no mention is made of current disassociated from the spark delivered to the person, nor prior to my own had any electrodes been shown by which a current, except in spark form, could be developed from a Holtz or other influence machine. When, in general, nerve and muscle reactions were spoken and written of, reference was had to galvanic and to faradic currents from coils and voltaic cells, or from coils and magnets, but not to any current derivable from frictional electricity. The spark and static electricity had become synonymous terms. That no one during more than one hundred and fifty years should have sought out the kinetic or current feature of the static discharge (in other than spark form) and harnessed it to an electrode capable of bringing it into use, seems most remarkable—the more so since my kinetic form produces a far greater and more powerful nerve and muscle stimulation per second than the spark form, and if discovered before the days of the secondary coil would at once have brought the frictional machine into the front rank of current administrations.

My new system, published and unpublished, comprises the development by an influence machine of a rapidly interrupted and graduated current, by means of a circuit breaker, introduced into a circuit with and without condensers, and in the medical applications of this current without and within the human body by moistened sponge or other electrodes, just as in the case of the ordinary galvanic and faradic currents.

It involves the removal of the spark, in itself more or less disagreeable and painful and often difficult to localize, especially about the face and neck, away from the patient's body, and yet retaining all the physiological effects of the kinetic or current part of the circuit. The spark is no longer a direct feature of the administration; it occurs at some distant part of the necessarily closed circuit, and in modified form now becomes mainly a regulator for timing the discharge of the equalizing potentials.

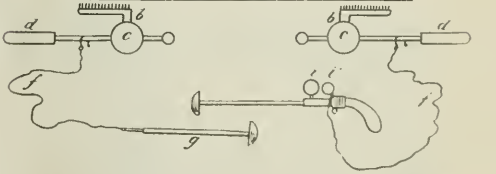

FIG. 2.—Static Universal Electrode. Interrupted primary circuit of a Holtz Machine, without condensers. Parts lettered same as in Fig. 1. *i*, *i*, Static universal electrode in circuit. Upon grasping the two electrodes and drawing the two brass balls *i*, *i*, of the circuit breaking electrode apart a current is felt causing vigorous muscular contractions in ratio with the distance apart of the balls *i*, *i* and as long as sparks will pass between them, in contradistinction to no reaction produced in Fig. 1. Patient insulated. Method applicable to small machines. With large machines method illustrated in Fig. 1 is recommended.

The circuit-breaker is a pair of adjustable metallic ball electrodes, introduced at any point of the circuit, having a narrow air space between the balls; the circuit "makes" when a small spark overcomes the resistance of the intervening air, and "breaks" when it fails to do so, and the current is due to rapidly successive equalizations of the differences of potential of oppositely charged condensers, whether prime conductors or with the addition of Leyden jars. The circuit-breaker serves:

1. To afford time (infinitely brief) to the prime conductors and condensers, if used, to charge.

2. To regulate the frequency of the discharge and col

[1] Read before the New York Neurological Society, Dec. 2, 1890.
[2] Read before the New York Academy of Medicine, March 3, 1881. See New York MEDICAL RECORD, April 2, 1881.

laterally the frequency of the succession of transient currents, so that their aggregate may be classed as a steady current.

3. To determine the strength of the current. This latter may be varied at will and with the utmost nicety, from a just perceptible to a most powerful effect.

The spark circuit-breaker now practically represents the vibrator in the primary of an induction coil; the

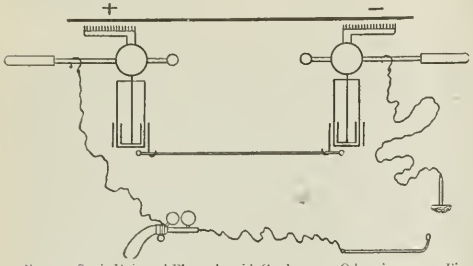

FIG. 3.—Static Universal Electrode, with Condensers. Otherwise same as Fig. 2, but current more powerful. Small condenser preferable.

specific inductive capacity of the air replacing the spring and its magnetic attractability and I use it as in that example and in the same relations, *i.e.*, to interrupt the primary current or by reason of an interrupted primary to obtain a secondary current.

I thus put the use of static electricity on a comparable basis with the other two forms of electricity, the galvanic and the faradic; in short, it becomes kinetic, flowing or current electricity. For just as the infinitely rapid suc-

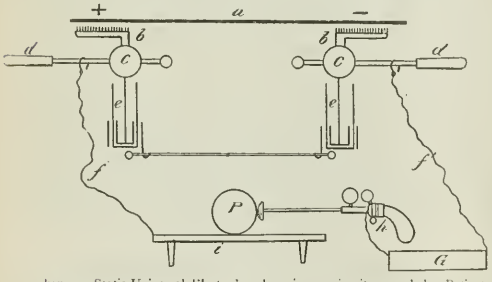

FIG. 4.—Static Universal Electrode. In primary circuit grounded. Patient, condensers, and circuit-breaker in same circuit. Patient on an insulated platform as in giving sparks. *f, f.* Grounded pole of machine and connection to platform; *P*, person insulated; *G*, grounded chain from universal electrode, having curved handle, to be held by administrator and applied upon the person of the insulated subject, strength of current graduated by the finger and adjustable balls of circuit breaker. (See Figs. 6 to 14.)

cessive chemical action in a voltaic cell sets up a similarly rapid successive propelling electro-motive force, termed in its aggregate in a closed circuit a "steady" current, so in this new form, by parity of reasoning, the constantly accumulating potentials, regulated by the sparking circuit-breaker in a remote part of the circuit, discharge with sufficient rapidity to also justify the application "steady" to that succession of impulses, any one of which in its single form is termed a transient current. The current of the induction coil offers a still better parallel. It is a rapid succession of electric impulses, each transient by itself, but taken as a whole steady, and sufficient to maintain a continuous muscular contraction or other effect. Accepting the fact that the rapidity of succession of impulses of the new current is in itself sufficient to produce a steady current, we may now go a step further and say that each impulse in itself consists of a vast number and range of oscillations or alternations (of one hundred millions, for instance, per second), and, putting all the facts together, we may doubtless willingly concede that a current whose physical properties so positively differ from other currents must possess equally positive and differing physiological properties. But we will refer again to these properties later on.

It is too much the custom in medical text-books to make an arbitrary distinction between statical and dynamical electricity. Such a hard and fast line of demarcation in electro therapeutics is misleading. Medically, in static or any other form of electricity, we have nothing to do with the electro-statical phenomena, viz., with stresses and strains set up in insulating, or rather dielectric media. The only thing we have to deal with is current, *i.e.*, electricity propelled along conductors by electrolytic or metallic conduction. The most modern views of electricity are, that what we call electricity is a specialized form of vibration

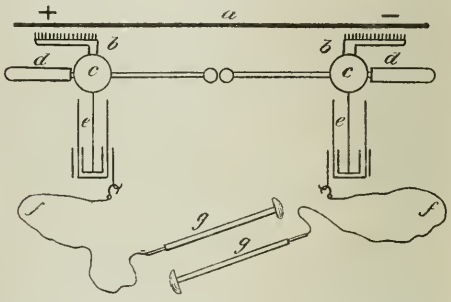

FIG. 5.—"Static Induced Current." Parts of Static Universal Electrode Separated. Person, condenser, and circuit-breaker in same circuit, connecting-rod between condensers removed, and discharging-rods of machine serving as circuit-breaker; but the circuit-breaker is in the primary circuit, and the person in the secondary. The make and break in the primary is accompanied with a current in the secondary.

of the ether which pervades all space and matter. The vibrating ether may be entangled in certain kinds of matter (insulators or dielectrics) and we then have a displacement or strain of this substance (electro-statics), or the dielectric may dissipate its strain in certain other kinds of matter called conductors, and we then have current (electro-kinetics). In franklinization, the stress, strain, or charge is only a condition precedent to the breaking down of the strain (spark) by a rupture of the dielectric (air) and its dissipation along the most convenient conductor (the human body). It is to the current, then, of a statical electrification that we look for a therapeutic effect, not to the electrification itself, and this current we get in a momentary form at every discharge of the electrification, or in steady form, in my own system, of a very rapid succession of momentary impulses, determined by the spark circuit-breaker. The simple charge of a Leyden jar will illustrate our point. For it practically includes the entire domain of electricity; the charge

FIG. 6.—Internal Administration of Sparks. *b*, Electrode; *a*, insulating tube perforated for passage of spark and currents; *c*, guiding handle for regulating length of spark and currents.

of the jar includes electro-statics or electricity at rest, or electricity in strain; its discharge, electro-kinetics, or current electricity, or electricity with the strain dissipated. Medically we use the discharge (spark, current), a point strangely lost sight of by some writers, who, confused by the term static, claim that the treatment is static, *i.e.*, a surface charge, *i.e.*, superficial, and that no effect therefore can be produced beneath the surface. It is time now

that this delusion should be dropped and the fact be frankly admitted that electro-statics in practice will give the physician a current that will demonstrably penetrate the human tissues as deeply as it can be demonstrated that any other current will penetrate them.

insulated), and circuit grounded (best method for external administrations), and

2. By including the circuit-breaker in one circuit and the patient in another, viz., in an induced or secondary circuit (Fig 5).

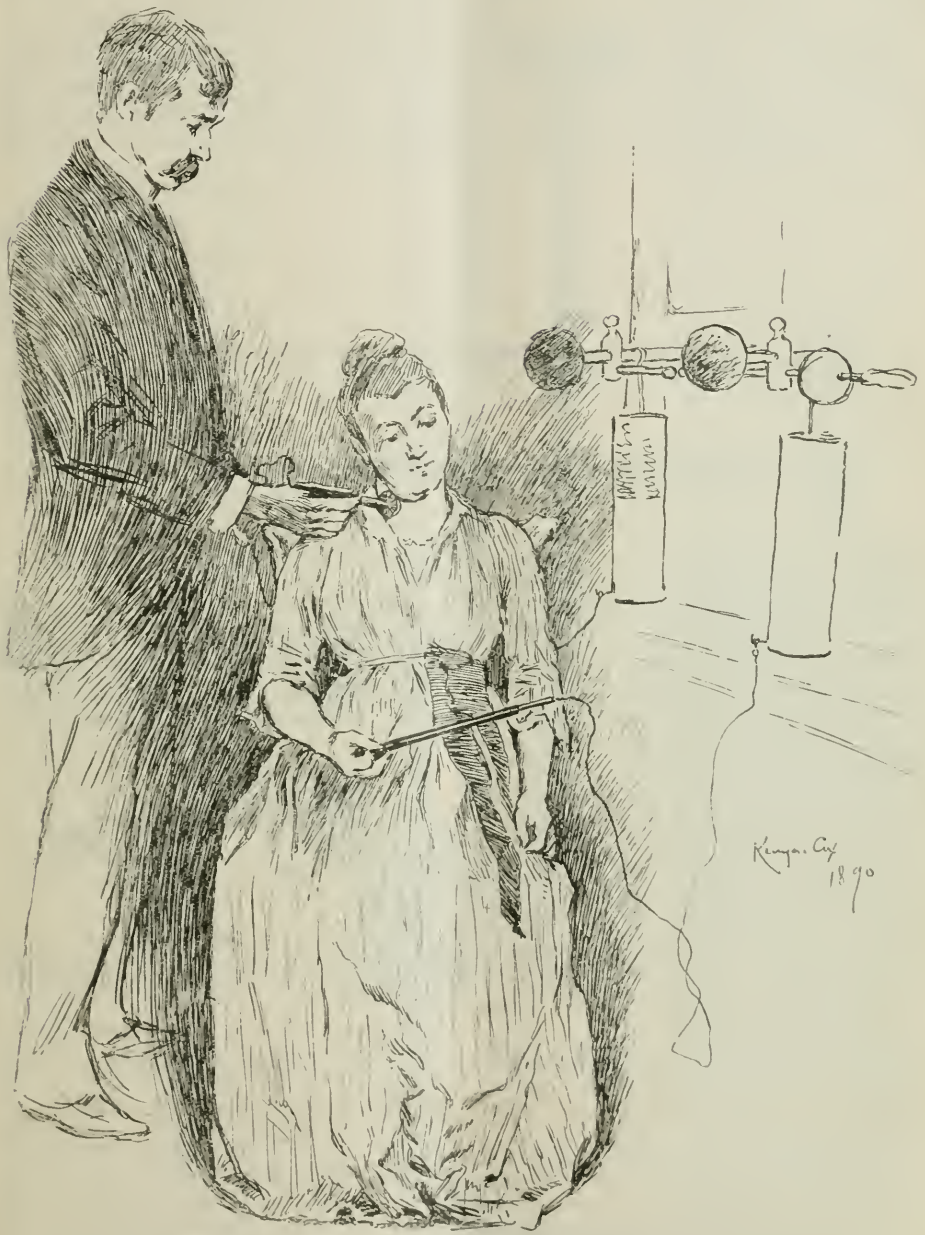

FIG. 5.—Method of Application of the Static Induced Current. One electrode applied to sterno-cleido-mastoid muscle for illustration.

In practice, the electrical principles involved may be carried out by two main methods.

1. By including the circuit-breaker and patient in the primary circuit, with or without condensers. Fig. 2 (without condensers), Fig. 3 (with condensers), Fig. 4 (patient

In both methods sponge and metallic electrodes are used externally or internally, as in ordinary galvanic or faradic treatments. For the former, I have invented a special electrode, for the latter I use the 1880 combination of the parts of the machine as a circuit-breaker.

As I have pointed out in a recent article [1] the spark is not to be regarded by itself and as a mere mechanical and superficial phenomenon like the blow of a light hammer, but as the air part of the closed circuit, whose remaining parts within the body (and in the connections and machine) evoke the well-known nerve and muscle reactions. But effective as this spark direct to the skin is, it has, as might be expected, its quota of disadvantages, among which may be mentioned, the relatively small number of spark currents provokable in a given time by a ball electrode, the more or less painful feeling in the skin, the possible humidity of the air, or of the patient's person, the difficulty of localizing it about the face and neck,

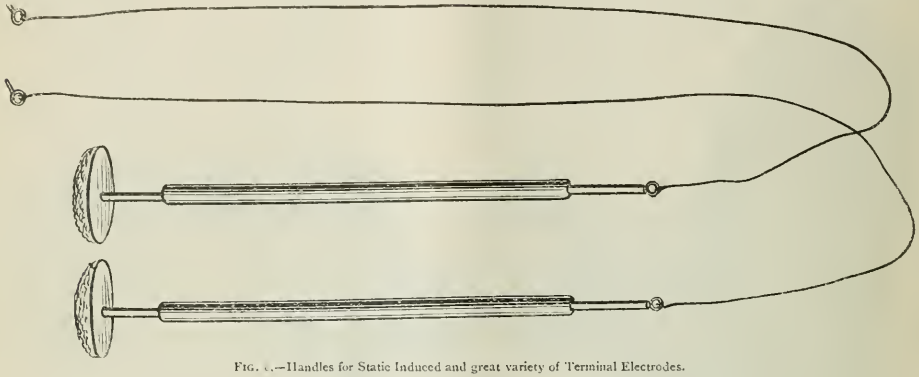

Fig. 6.—Handles for Static Induced and great variety of Terminal Electrodes.

and finally, and most important, the comparative difficulty of using it at all for throat, uterine, and other internal treatment. For these reasons I supplement the usefulness of the Holtz machine and its usual spark administration, and have devised and formulated the present system. Its fundamental principle, as has been pointed out, is that of interrupting the circuit at a point remote from the patient, while still including him in the circuit. And although the static induced current was published, a most useful and important element in the system, and one embodying in itself, in a simple and practical manner, all the principles involved, viz., the statical universal electrode, has only appeared in the catalogues of instrument makers, while concerning the internal use of the franklinic current nothing has been said. It seems therefore advisable now to collect the scattered data and present the system as a whole and as constituting a new system, particularly since no attempt has before been made to formulate the details of mechanical arrangement under one general statement, nor to differentiate the nature of the current and its physiological effects, beyond the general and, in the opinion of the writer, most superficial comparison of the current to the faradic.

The illustrations in this article will serve to indicate the principal connections referred to.

A current may also be obtained by attaching one cord to one prime conductor (with condensers) and the other to the outer coating of the condenser on the other prime conductor, but it is harsh and lacks the good qualities represented by connections as in Fig. 5.

Fig. 1 is shown merely for illustration. There being no circuit-breaker there is no perceptible current. Figs. 2 and 3, though representing perfectly practical connections, especially with small machines, are best replaced in practice and with large machines by Fig. 4.

Fig. 4 represents a working method hitherto undescribed, except by cuts in the manufacturers' catalogues (as early as 1881), embodying, in the simplest and most practical manner, the fundamental principle of my new system, viz., the interruption of the circuit at a point removed from the patient.

[1] New York Medical Record, May 31, 1890.

Fig. 5 represents the secondary current, termed by me the "static induced current," elsewhere referred to. On the whole I give my preference in most forms of treatment to the connections represented by this figure. It will be readily seen that any kind of electrode may be readily attached to the terminals.

Maintaining as I do in practice a continuous action of the machine by water-power, I often find it desirable while making a change in the position of an electrode, Fig. 4, to shut off the electricity without stopping the machine. This I do by simply short circuiting the prime conductors. This procedure obviates the slight spark which inevitably ensues on approaching the electrode to its position, unless this is done while the machine is at rest.

Though here not in line with the exact subject-matter of this paper, I furnish an illustration of an electrode made in a variety of sizes and forms, by aid of which sparks may be administered to the cavities of the body. Though long in use by myself a description of it has not before been generally published. Its applications are manifest, and its modifications manifold, according as it is desired to apply a spark along the urethral canal, to the uterus, throat, or other internal cavity. It may also be used to exactly localize the sparks upon the exterior of the body.

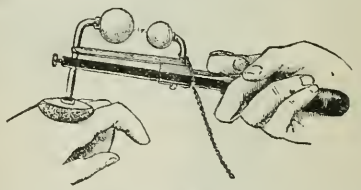

Fig. 9 represents this electrode as constructed in 1880; arranged for a moistened sponge or other terminal. The two adjustable brass balls constitute the circuit-breaker, the spark passes between the two and a corresponding current produces characteristic electric reactions at the point of application of the sponge to the body.

Static Induced Current.—For this current the electrodes and conducting cords must be especially constructed; the metal within the sponge, if a plate, should be rolled back on itself at its edges so as to present a rounded peripheral contour, or, better still, it should be a ball of about one inch in diameter; the handle of the electrodes should be long, and made of ebonite; the conducting cord should consist of a thick strand of fine wire well insulated by gutta percha. These precautions are necessary, owing to the great "tension" of the current and its consequent disposition to break down insulating barriers which in the case of ordinary currents would suffice to confine them to their proper conductors.

To use the current (see Fig. 5), bring the discharging

rods of the Holtz machine into contact, remove the connecting-rod which unites the two Leyden jars, and hook on the two conducting cords and electrodes. The patient need not be insulated. If now the wet electrodes be grasped, the machine set in motion and the discharging rods be separated a very small fraction of an inch, the current will be felt and may be graduated to any strength desired or bearable, and may be localized in its application internally or externally in the usual manner. In this connection I quote one of the concluding summaries in my article read in 1881.

"Ninth. The invention, by the author, of a method of obtaining an interrupted static induction current from a frictional electrical machine adds to medical electricity a new and practical means of electrical treatment."

Static Universal Electrode.—This electrode is so named because the administrator may, by a simple motion of the finger in operating the circuit-breaker change his treatment from sparks to current, and vice versa, and because a great variety of terminals may be quickly attached to it, adapting it to the customary forms of application desired for galvanism and faradism. It will be recognized as a great convenience in a single sitting to turn at once from the spark treatment to an agreeable, regulatable, efficient current for use about the face and neck, and wherever else desired to uncover the skin or to introduce, by adding a suitable terminal electrode, within a canal or cavity.

Physical Properties of the Franklinic Interrupted Current.—I have thus far been unable to find any description of this current prior to my own. And medically it is positively certain that it never had been employed. The statement as usually made is as follows:

"Effects of the electric discharge? The recombination of the two electricities which constitute the electrical discharge may be either continuous or sudden; continuous, or of the nature of a current, as when the two conductors of a Holtz machine are joined by a chain or a wire; and sudden, as when the opposite electricities accumulate on the surface of two adjacent conductors, till their mutual attraction is strong enough to overcome the intervening resistances, whatever they may be." [1]

In the one case, the continuous discharge, we have a current physiologically and clinically producing no effects. For, as is well known, we may hold both hands upon the prime conductors of the most powerful Holtz machine and allow the entire current to pass through our bodies without experiencing the slightest electric sensation.

In the other case, the sudden discharge, we have to deal with the disruptive effects seen in the spark from charged conductors and Leyden jars, now so long the common means of medical administrations. The franklinic interrupted current is neither the sudden and transient form (spark or shock) nor the ineffective, continuous flow, but, as has been pointed out, it is a succession of relatively small, sudden discharges, and it produces the permanent effect of physiological tetanus. It therefore stands distinct and by itself as capable of producing a result unattainable by either of the forms mentioned in books. The comparison to the current of an induction coil or of a dynamo is not an exact one, except as to the point of a rapid succession of interruptions. In the induction coil and the dynamo the series is made up of single impulses, or currents in opposite directions. In the Franklinic interrupted each impulse consists of a series of alternating opposite currents of almost inconceivable rapidity. Joseph Henry discovered that each discharge of a Leyden jar was oscillatory in character, not a single transfer of electricity from one side of a jar to another. In making his original statement, he wrote, there is "a principal discharge in one direction, and then several reflex actions backward and forward, each more feeble than the preceding, until the equilibrium is obtained." His discovery was corroborated, and the theory of it worked out by Sir William Thompson, Feddersen, Helmholtz, Schiller, and others. As now stated by eminent physicists, the number of alternations to each spark is from one hundred thousand to one hundred million per second, according to the capacity and inertia of the circuit. Induction coils have been constructed, giving eight thousand vibrations per second; two hundred per second is probably an average of the medical faradic coil. We cannot, therefore, compare the franklinic interrupted current to such coils.

For computing the spark interruption to be at the least two hundred per second, and the oscillations of each spark to be one

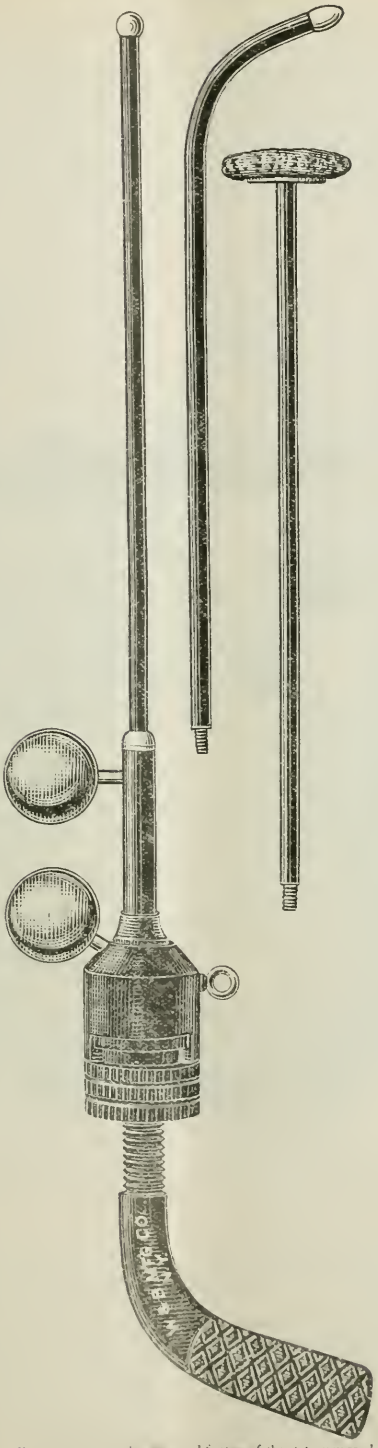

Fig. 10 represents the latest modification of the static universal electrode with a number of terminal attachments. From the shape of the handle this was termed by the manufacturers, and I in want of a better name, the pistol electrode.

[1] Ganot's Physics, p. 674.

hundred millions per second we have a current giving twenty billions alternations per second. Vast as such a number may seem to our minds, familiar with two hundred vibrations per second, it pales before the desideration expressed by Professor Elihu Thompson, the great authority on the properties of alternating currents, who said in a recent lecture, "What is needed is a machine having an alternating current making five hundred trillions of vibrations per second, which would produce many wonderful results." If, then, I were to be asked how the Franklinic current differs from the ordinary Faradic coil I should reply that this one difference of rate of alternations alone placed the two far apart. But, it may be urged, the current of the induction coil is far greater than that of the influence machine in quantity. This is of course true. But at this point in favor of the Franklinic interrupted comes in the element of time. "The motor nerve," says DuBois Reymond, "is not stimulated by the absolute density of the current density at any given moment, but by variations from one instant to the other, and the effect produced by these rapid changes increases with their rapidity and their greatness in a given time." Thus, in the great rapidity of the alternating (oscillating) currents of the spark discharge, particularly in rapid series as in the Franklinic interrupted, we find the reason despite smallness in quantity for accomplishing work in producing nerve and muscle stimulation, equal at least to the comparatively slow discharge, of the interrupted galvanic, or the slowly oscillating induction coil. The difference may be compared to a bullet shot from a rifle or the same bullet gently rolled across the floor.

I have at least made it clear, I trust, that the new current is strongly differentiated from the galvanic or faradic currents, and taking into account its enormous voltage or pressure of 53,000 per linear centimetre, viz., its power of overcoming resistance in the human body conductor, and its other characteristics as above pointed out, we have a right to expect in its medical applications physiological effects differing from those of the other electric currents thus far brought into medical use.

Among other purely physical experiments I have made I will mention that it produces a loud and clear sound in a telephone resembling the sounds made by an induction coil.

Clinical Properties and Medical Uses of the Franklinic Interrupted Current.—Since we are dealing with a current and not a spark, and with the familiar sponge or metallic electrodes, we may invade the entire field traversed by galvanism and faradism, and ascertain for ourselves such differences and similarities as may exist.

Applied to a motor point, the Franklinic Interrupted Current produces most vivid and persistent muscular contraction with a minimum of pain; applied farther back on the trunk of a motor nerve it throws large groups of muscles into contraction. The contraction is peculiarly painless as compared with that of faradic coils, and the influence is remarkably diffusive. Accompanying a contraction of a large group of muscles is a peculiar sensory sensation of lightness and buoyancy of the member. The painlessness, diffusiveness, and buoyancy may all be experienced by holding the two electrodes in the hands, and taking a current as strong as possible. Most people will readily submit to flexions successively at the wrists, elbows, and even to the shoulders before insisting upon taking no more. The arms during the passage of the current feel as if made of cork, and this feeling of lightness persists for some time. It is the same feeling doubtless, though here exaggerated, as is commonly referred to as the refreshing effect of general electrization. The quality of the current is such, that while energetically exciting the motor function of the nerve-filaments, it fails to excite or may even annul, to any extent, the sensation of muscular pain. Its penetrating, diffusive, painless effect, with strong muscular contractions, adapt it admirably to general application over the entire body as an electric in place of an ordinary massage.

It is, of course, applicable to every form of muscular paralysis, for there is no practical stimulus to nerve and muscle except the electric, and none more energetic than this form of it.

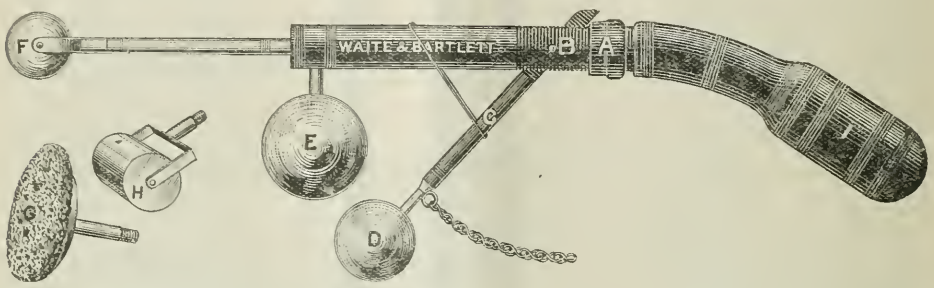

FIG. 11 represents the electrode as now modified and supplied with a variety of attachments, such as sponge, brass ball, throat, urethral, prostatic, rectal, vaginal, uterine, and stomach.

Its effects upon the Hallerian irritability of the muscular tissue necessarily includes an effect upon the local circulation of a part and upon the lymphatics, and to this may doubtless be referred many clinical results of relief, as in lumbago and all forms of muscular rheumatism, subacute and chronic rheumatic affections of the joints, ovarian or pelvic pain, sciatica or other neuralgias.

The second prominent characteristic of this current is its power of relieving pain. Leaving out of sight the part, be it more or less, played by circulatory changes referred to, in this respect there seems to exist a specific analgesic quality in the current. The cotton feeling in the hands, and subjective sense of buoyancy in the arms, is in itself an evidence of this. But the effect upon pelvic pain, upon ovaritis, upon neuralgias, pleuritic "stitches," tonsillitis, and many other pain affections is still better evidence. In sciatica, for instance, the sensation of pain is frequently quickly relieved and a cure obtained, though I think in this case the cause is twofold, that is to say due to both the circulatory and the analgesic effect. The same I believe to be true in the pelvic and ovarian pains.

The results in such cases, in my opinion, are far superior to anything attainable by a faradic or a galvanic application. An ordinary faradic current will increase the pain, the galvanic will very often relieve it. But we have in the Franklinic interrupted no comparison to the electrotonic and polar effects, or in general the electrolytic effects of the galvanic current. Therefore, when the Franklinic interrupted has failed to act favorably, we should try the galvanic, and vice versa. As no observations on the purely analgesic effects of this current have hitherto been made I must leave others to test the question for themselves. And as the paper is not clinical, but simply to outline the subject in a general way, I can-

not burden it with cases which I might give in large numbers.

The motor effect, including the circulatory, cannot be denied; the pain-annulling effect, though clinically demonstrable, is difficult to explain. Perhaps the extraordinary frequency of the alternations of the current per second may explain it. These alternations, it will be recollected, I computed might easily amount to twenty thousand million per second. My own view is that the and fallen under the influence of the stronger vibratory influence. Again, a vibrating tuning-fork may lose its motions by reason of the interfering vibrations of another more powerful one and finally vibrate in unison with it. Or electrically a stretched platinum wire may be thrown into visible vibration by the alternating current which at the same time heats it to redness. Medically I venture the suggestion that the nerve-filaments are set into similar vibrations, and that these overcome the pain, not by coun-

FIG. 12.—Electric Connections and General Method of Administration by Static Universal Electrode. In the cut the wet sponge electrode is applied for example to the facial nerve with characteristic reaction.

great frequency, the fineness, so to speak, of the electric vibrations, which we know as a matter of fact are set up in the nerve-filaments, interferes with and annuls the pain impulse. The carbon filament of a glowing incandescent electric lamp, situated ten feet away from an influence machine discharging sparks, was seen by Dr. H. E. Waite to break. It had evidently been thrown into violent vibration. If it had had a vibration of its own before being subjected to the electric vibration it would have lost it

ter currents, as I understand is the suggestion made by Apostoli, but by simple agitation of the mass of the constituent elements of the nerve-fibre, and thus an annulment of its capacity to conduct pain impulses, just as concussion or anæsthesia of brain-tissue may be said to annul its capacity to respond to sensory impressions. The experiments of Mortimer Granville with his percuteur taught us the benumbing influence upon painful nerves of even coarse vibrations. With alternating electric impulses

of twenty thousand millions per second, more or less, we may find explanation of the analgesic effect of the Franklinic interrupted current. Furthermore, its static quality would enable it to set up an influence in anatomical parts regardless of the intervening medium, as witness the action of the Phelps-Edison induction telegraph, where an inductive circuit sufficient to work a telephone may be set up across an air-space of even forty feet. Surely the analogies of electro-physics are safe guides, and the only safe stand-point from which to study the action of electricity upon the human body.

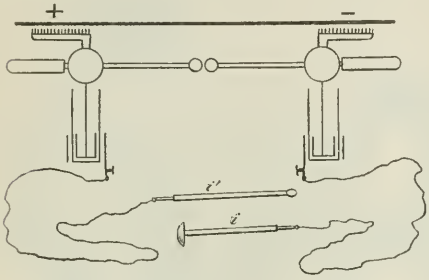

FIG. 13.—Diagram Illustrating Connections for Internal Treatment by the Static Induced Current. *i*, Indifferent electrode; *i'*, interior electrode.

Another effect upon sensory nerves is the production of a sour taste when the current is applied to the tongue, and of slight waves of light when applied about the eye.

Gynecologically my system of conveying the current within the cavities of the body opens out a wide and promising field of clinical results. To improve the nutrition and remove the pain in and about pelvic organs, in itself covers a large number of conditions of the uterus and its appendages, not yet so thoroughly combated as to allow anyone to say that he can do without an agent so potent to relieve pain and restore local and capillary circulation and set up favorable nutritive changes as the Franklinic current has demonstrated itself to be.

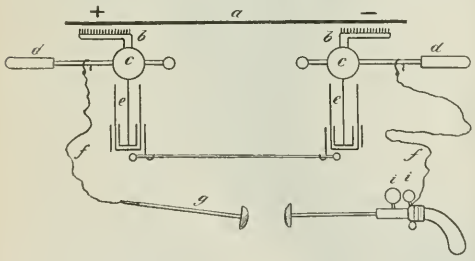

FIG. 14.—Diagram Illustrating Connections for Internal Treatment by the Static Universal Electrode.

Finally, I may say, as a result of a very considerable experience, that this current penetrates as deeply into the human body as even the galvanic, and I have no doubt that tests may be devised to demonstrate that this is a fact. It will not be one of the unusual retributions when it turns out that static electricity, now frequently referred to as superficial and incapable of affecting the deeper tissues, is accepted as being the most efficacious electric means we possess for reaching those tissues.

I shall be content if my contribution of the Franklinic interrupted, and its wide range of internal and external uses, shall help to place electro-statical in that front rank of electro-therapeutics where I believe it should be.

Dr. Ambrose L. Ranney, to whose able writing the subject of electro-statical therapeutics owes much, very kindly remarks: [1]

"The greatest event, after its discovery, in the history of medical statical electrization or franklinism was the invention of the Holtz or induction machine, in 1865. Next in importance, perhaps, is the method discovered and put into practice by Dr. Morton, in 1880, of converting the static discharge into a dynamic discharge or current; and the electrode represented in the above cut [Fig. 10] is the only novel electrode of any importance not bequeathed to us by the medical electricians previous to 1880."

In conclusion, what is here brought forward as new is:

1. The generalization of what I announced as an isolated fact in 1881, that a regulated interruption in the otherwise inoperative circuit of a Holtz machine would produce in another part of the circuit a current adapted to electro-therapeutic practice. This current I now designate the Franklinic interrupted current. It includes the adaptation of the parts of a Holtz machine to produce this result.

2. A new electrode combining this current with various terminals.

3. The practice of introducing Franklinic electricity in current form into the interior cavities of the human body.

In short, a new system of the therapeutic administration of Franklinic electricity in contradistinction to tha system by sparks and its necessary limitations so long in vogue.

19 EAST TWENTY-FIGHTH STREET.

[1] Static Electricity in Medicine, etc. The Physician and Surgeon, July and August, 1887.

DISEASES OF NORTHERN CALIFORNIA INDIANS.

BY LIEUTENANT CHARLES E. WOODRUFF, M.D.,
MEDICAL DEPARTMENT, UNITED STATES ARMY.

Consumption.—An experience of a year and a half among the Indians of Hoopa Valley, Cal., has shown me the extent and malignancy of this disease, particularly among the young people. I do not bring forward any new phases of the affection, but a recital of certain points may be of use for comparison with reports from other sources. A study of these people, and of some other tribes in different parts of the country, may possibly shed some light upon the influence of civilization in developing disease.

The advent of white men is of so recent a date here that one would suppose it an easy matter to determine whether or not consumption was prevalent before that time. There are scores of men and women in this neighborhood along the Klamath and Trinity Rivers who had reached maturity before the white man was seen, and who certainly know something in a general way as to the mortality of the people and the diseases from which they suffered. The difficulty in the inquiry is attributable to the fact that the average Indian is much given to lying. With a profound and serious air, his hand on his heart, and calling on mother earth to witness, he will utter statements at manifest variance with the facts. Some Indians seem desirous of proving that they were better off before the time of the white men; and these have solemnly assured me that in former times disease was a rare thing; that but for occasional accidents in the way of starvation in severe winters, all the people lived to a good old age in the enjoyment of perfect health, and that nothing similar to consumption was known. Others, on the contrary, have assured me that they have always suffered from a fatal disease in which there was a gradual wasting of the body with an uncontrollable cough. Without any suggestion they have volunteered the information that this "must have been consumption." The native doctress is reticent, but if she would talk could probably give little or no information.

They considered disease as a specific entity, probably an evil spirit within the body, causing pain, and to be drawn out by sucking the painful part. The doctress usually goes through various incantations, accompanied with vomitings of froth, probably to indicate that the disease

was absorbed by her and then vomited up; she never looks for symptoms, and is probably unable to tell the difference between consumption and cholera morbus.

Taking for granted that the Indians did formerly suffer from consumption it is a fact that at the present time the disease is exceedingly prevalent and fatal. During my short period of observation I have seen whole families wiped out of existence, the children having been indiscriminately attacked and actually hustled into their graves. It is among the half-breeds, white father and Indian mother, that the greatest mortality is found; the fathers in such cases have been robust and have outlived a numerous progeny.

The susceptibility of the Indian, and particularly of the half-breed, to the diseases of civilization, seems to be most marked in the case of tubercle. To all appearance he may be the picture of health, robust, powerfully built, and possessed of remarkable energy, but let the bacillus of this disease lodge in the lungs and he is seen actually to melt away.

I may refer, in passing, to two apparently strong and robust full-blood women aged about seventeen. These girls contracted consumption after they were photographed, and about six months later one died of the disease, followed in two months by the other.

In view of the contradictory statements it is impossible to decide whether the whites introduced the disease, or by the introduction of enervating habits and syphilis have made it more fatal. It is just probable that the disease has always had a home here, but that its spread was checked by a mode of life almost exclusively out doors. The sick did not survive long enough to be a continued source of contagion, as in cases where modern methods prolong life and facilitate the transmission of the tubercular infection.

The changes wrought by the whites are certainly to some degree responsible for the increased prevalence. The Indian has taken to the clothing, food, and shelter of the whites, but adheres obstinately to certain habits. Formerly while naked he was so inured to cold and sudden changes in temperature that minor ills were probably rare, although pneumonia, I have reason to believe, was not uncommon. By clothing himself he has lost this acclimation to exposures, and has so degenerated as to be less resistant than a white man under similar conditions. Formerly an Indian would wade through mud and water with impunity, for in a few minutes his naked feet and legs would be again dry; now, when clothed and shod, he does the same thing, but he has not learned to change his clothing, and will stand idly around until his clothing dries. Now, also, being less resistant to cold, they crowd together in their rooms for warmth, and a consumptive among them has every facility for spreading the disease.

The question of food is also of importance. Formerly the food was of good variety and adequate to all nature's needs. Salmon, acorns from which nutritious soup or bread can be made, venison, and a large variety of roots, berries, bulbs, and grasses constituted a reasonably generous diet. In taking up the pioneer's bacon and beans they have in some cases forsaken their own better diet. I saw one well-marked case of scurvy, and on inquiry found that the squaw had lived for months on an almost exclusive diet of bacon; but she quickly recovered on a more generous and anti-scorbutic fare. It is not impossible that in the transition to a new dietary their constitutions and powers of resistance become weakened. Yet aside from these adverse conditions there seems to be something in the general constitution of these Indians which makes them extremely liable to contract the disease.

The children that have been taken into white families and raised as servants are an illustration of this. These have originally possessed vigorous health, but after several years of civilization under the best conditions, good food, good clothing, and excellent care, they fall into consumption and die. It was said by a physician of my acquaintance that to take an Indian girl into service is to pronounce her death sentence. This of course is an exaggeration, as I know many Indians raised by whites who are now strong and healthy.

Inasmuch as the climate is favorable, one would expect that incipient cases under proper conditions should get well. I have had under observation for more than a year a case of incipient phthisis in a half-breed whose father is a wealthy ranchman and can afford to produce those conditions which a consumptive should have. This young man is evidently getting better, his cough has subsided, he expectorates no blood, his weight is largely increased and the area of dulness is not so large nor so well marked. Another case, a white woman, has greatly improved. Among poor Indians I have seen but one case which has not progressed rapidly. This man had well-marked dulness with harsh respiration and prolonged expiration eighteen months ago; yet he is now a strong healthy man.

All forms of tubercular diseases are found among the Indians, synovitis, meningitis, peritonitis, and tuberculous glands in the neck accompanying tuberculous lungs, and in many cases the addition of inherited or acquired syphilis aggravates the condition of the individual. Few cases of deformity from tubercular diseases of the vertebra are to be seen. I recall three only; two of them adults at least thirty or thirty-five years of age.

Syphilis.—The evidence that the Indian did not have this disease in former times is somewhat more reliable than in the case of consumption. The infection seems to have been introduced by whites in 1851, and now a large percentage of the Indians have become infected. Although cases of tertiary syphilis are frequently observed there is a remarkable paucity of primary and secondary cases. It is my impression that the Indians do not show the usual secondary symptoms seen in whites. After the primary sore and the enlarged glands appear in the groin not much may be seen until gummata are developed.

Of course the results of syphilis are to be seen broadcast. Blindness or partial blindness from this and gonorrhœa may be found all over the country. One-eyed men are more frequent than among whites, though many of these cases are due to traumatism. I have treated a severe case of syphilitic iritis which had been under the care of an ignorant man who did not recognize its nature, and who allowed it to proceed a long time without specific treatment.

In another case I was particularly struck with the immense depressions and holes in the cranial bones, sternum, and tibia, where gummata had healed.

It is of interest to the sociologist to determine whether syphilis or tubercle has a greater responsibility for the smallness of the Indian families. I do not know of a single family of more than four children; I know of many with only one or two, not that the birth-rate is small but that the mortality of infants is large.

Gonorrhœa.—There seems to be reliable evidence that this also is an importation; without exception all the Indians declare it to have been formerly unknown. At the present time this country may be regarded as a hot-bed or culture-ground of gonorrhœa. There is scarcely a squaw under sixty who has not had it. The men accept it as a matter of course, just as the whites accept coryza as a necessary evil.

As with syphilis, the results are spread broadcast. Stiff joints from gonorrhœal rheumatism (and white swellings also) and ruined eyes from gonorrhœal conjunctivitis are not uncommon. The Indian neglects this trouble as soon as he is free from pain and inconvenience, and it is probable that the strictures which surely now exist will be heard from within the next ten years.

It is needful merely to remark that venereal warts and chancroid are a concomitant in many cases and often exist by themselves.

Rheumatism and Neuralgia.—The careless habits of life of the Indians would lead us to expect that rheuma-

tism and neuralgia were common, and such is the case. The Indians are a people of aches and pains. I believe I have seen every form of rheumatism, from the acute articular disease to simple muscular pains.

In the acute affection the duration of the disease is longer than in the case of whites, but is remarkably short considering the habits of life and the long period of wet and cold weather, from November to April.

A remarkable characteristic is the ease with which they "give up" in the milder attacks of muscular pains, and the persistence with which they will remain in bed or inactive. One middle-aged woman kept to her bed during the whole winter with a lumbago which I am morally certain was not severe, and she hobbled on crutches long after the mild weather came on and complained bitterly until, with the advent of the dry season, every vestige of pain disappeared.

Lobar Pneumonia.—The cases of this disease that I have seen occurred in summer. It differs in no respect from the affection in whites. One case died of starvation, for, in accordance with their usual custom, they will not eat when sick. This man was large and robust, but after ten days of starvation he became much reduced. By the effort of friends he was made to eat and was on the road to recovery, when, for a headache, he called in a native doctor, again refused to eat, and died a few days later.

Leucoderma.—The case of leucoderma (picture enclosed) is unique. I cannot learn that such a case has been heard of before among these Indians. The white spots began about a year ago, or probably longer, the patient's statement being unreliable. The legs are not so much involved as the body, and the back not so much as the chest and abdomen.

Conjunctivitis.—The native Indian huts have no fireplaces nor chimneys—a hole in the centre of the roof is made for such. As a result of this the smoke from the fire built in the centre of the floor fills the house and causes conjunctivitis. In some of the old squaws the condition of the eyes is wretched, the lashes having dropped out and the whole lid become a mass of granulations. As I have seen the same condition among other Indians, it may be common to all who have huts of their own construction.

The following cases are merely curiosities, as I have seen but one of each: A child of two years was brought to me with all the signs of acute polio-myelitis anterior. It had been sick for two months, and was now almost completely paralyzed in its lower limbs; huddling in a helpless condition in its mother's arms.

Another child of six or seven was a typical case of pseudo-hypertrophic muscular paralysis. The calves of the legs were quite large, but the muscles around the shoulder, breast, and arms, were much wasted. His waddling gait and sway-back position when standing were so characteristic that I regret exceedingly not taking his picture to enclose with this paper.

I take occasion in this connection to allude to a typical case of locomotor ataxia, in which all the usual symptoms, from the absent patella reflexes to the characteristic trophic ulcer on the heel were present. He is now barely able to move around, and when in the standing attitude he is compelled to brace a balance on his crutches that he may obtain four points of support to keep him upright. His upper extremities are also considerably affected, so that he even cannot use the crutch and cane except with great difficulty and awkwardness.

Ovarian Cyst.—One case of large ovarian cyst, from which ten quarts of fluid were withdrawn by tapping, has come to my knowledge. The fluid withdrawn was of specific gravity of 102, and contained numerous cells, among which were large round Drysdale cells, containing highly refractive granules. The woman was doing very well at last report, but the cyst is undoubtedly refilling.

Penetrating Gunshot Wounds of the Abdomen, with Recovery.—The following case of gunshot wound in the case of a half-breed, came to my notice, but not under my care. The bullet entered the back about two inches from the median line and two and a half inches below the margin of the ribs, and came out two inches to the right (?) and about two inches below the umbilicus. He had not a single untoward symptom, and recovered fully in about three weeks, without any special treatment. The bullet in its course had evidently escaped all important viscera, though it entered immediately over the position of the kidney.

Rhus Poisoning.—Although the whites are often affected by "Poison Oak," which grows in great luxuriance throughout this country, the Indians do not seem to be susceptible to its influence at all; indeed, they use the stems of the plant to make baskets.

The Black Teeth of Malays.—The Government of Brumah has lately published an interesting report by Mr. Merrifield on the prospects of planting in Mergui, in the extreme south of Tenasserim, in the course of which he corrects the common error that the black teeth of the Malays and Siamese are due to chewing betel mixed with lime. It appears that the black color of the teeth is due to a special process employed for the purpose, for no respectable Siamese would like to have white dogs' teeth, like Chinese, Indians, and Europeans. Cocoanut kernel is carefully charred, and then worked to a stiff paste with cocoanut-oil. When carefully and regularly worked over the teeth, this produces the black varnish which is so much admired. Among some Malay tribes it is considered the proper thing not only to blacken the teeth, but to file them down to points like shark's teeth. "A Siamese or Malay man or woman does not strike a European as beautiful when yawning."

HYPODERMIC MEDICATION IN DISEASES OF THE EYE.

By CHARLES J. LUNDY, A.M., M.D.,

PROFESSOR OF DISEASES OF THE EYE, EAR, AND THROAT IN THE DETROIT COLLEGE OF MEDICINE, OPHTHALMIC AND AURAL SURGEON TO HARPER HOSPITAL, ETC.

Hypodermic medication is by no means new to the medical profession. The hypodermic syringe, since its introduction by Alexander Wood and its improvement by John Hunter, has been used more or less extensively; but within the past decade its use has become more wide-spread, and it has been employed in many cases where formerly other means were relied upon. During the past fifteen years I have used the hypodermic method of medication, either alone or as an adjunct, in the treatment of a large number and variety of cases occurring in my ophthalmic practice. The results in most of these have been eminently satisfactory, and the cases of failure have been few. The total number of injections amounts to several thousand, which were administered either by myself or under my direction by my assistants, Drs. Arnold, Marvin, Campbell, and Roller, gentlemen who have been in my employ at different times during the past several years.

In not a single instance has an abscess formed, and discomfort or severe pain has been seldom complained of. In two or three instances, where an assistant failed to insert the needle sufficiently deep, slight ulceration of the skin followed.

In the main, the injections were deep, or what Dr. Bartholow calls parenchymatous injections, as distinguished from injections made just beneath the skin. The injections were made into the arms, thighs, and gluteal region, and the amount of fluid used at a time rarely equalled half a drachm. Large quantities of fluid are more likely to cause pain and discomfort.

The remedies which have been thus employed are strychnine, pilocarpine, ergotin, and several salts of mercury; and these have been administered in such diseases as amaurosis, choroiditis with hyalitis, detached retina, and syphilitic affections of the eye.

Amaurosis, or blindness, due to the effect of alcohol and tobacco, has long been recognized by the ophthalmic surgeon; but amaurosis due to the excessive use of tobacco alone has been denied by a few. Undoubted cases of tobacco amaurosis, however, have been observed and reported by such authorities as Sir Jonathan Hutchinson, Nettleship, Alt, Chisholm, Agnew, Noyes, Webster, Berry, Uhthoff, and many others.

Ophthalmoscopic appearances are not always characteristic in this disease, but central scotoma is frequently present and the color-sense is impaired in the vast majority of cases; and these points, together with a knowledge of the patient's habits, will often aid us in making a correct diagnosis. In tobacco amaurosis Hutchinson says that the nutrient vessels of the optic nerve become smaller and finally disappear, while the retinal vessels may be but slightly altered. In these cases I have never observed the peculiar capillary congestion of the optic disk and retina which is a characteristic of so many cases of chronic alcoholism, and neither have I observed that the atrophic changes are so well marked. Noyes considers that atrophy follows neuritis in these cases, and that the lesion may be at any point between the chiasm and the intra ocular end of the nerve. The optic disk is first congested, but the ophthalmic surgeon is not often consulted during this stage. Atrophy follows, with disappearance of the nutrient vessels of the disk. Sight may be slightly or greatly diminished. Central vision fails first, and the color-perception is generally early impaired.

In the treatment of tobacco amaurosis the hypodermic use of strychnia has proven itself of inestimable value. Ophthalmic surgeons have for years relied upon this method of medication, and have considered it superior to all others. My own experience coincides with that of other specialists, and bears testimony to the marked benefit to be derived from its use in such cases. Of the several cases which I have seen, the following is one of some interest:

Case I.- George B——, aged forty, Dresden, Ont., came to consult me on October 5, 1883. For more than a year his sight had been failing, and he could no longer see to read and write, or to shoot with a rifle, a sport to which he was greatly attached. Vision in right eye equalled $\frac{20}{100}$, in left eye $\frac{20}{200}$. Central vision not so good. Color-perception much impaired. Ophthalmoscopic examination showed the media clear and the optic nerve pale and slightly atrophic. His habits were good, except that he was a constant user of tobacco. He used no liquors whatever. My diagnosis was tobacco amaurosis. Daily injections of strychnia one-twentieth grain, were begun, and the dose was rapidly increased till one-fifth of a grain of the nitrate of strychnia was given once a day. The use of tobacco was prohibited. The improvement in vision was soon apparent, and went steadily on till vision in the right eye reached $\frac{20}{20}$, or normal, and in the left it was only a little less acute, being $\frac{20}{30}$. The patient was sent home, and given strychnia pills to be taken for some time. At the end of a year his vision remained good. Would this patient have regained his sight without treatment had he simply discontinued the use of tobacco? I think not; at least my experience has taught me that abstaining from tobacco alone is not sufficient to effect a cure in advanced cases. Even strychnia does not cure all cases where the sight is very poor and the disk is much wasted. In amaurosis depending upon the combined ill effects of alcohol and tobacco, it is a mooted question whether the alcohol or the tobacco is the more active agent in producing the changes to be observed. Chronic alcoholism produces marked changes in other nerve-structures, and I am fully persuaded that it also produces certain changes in the optic nerve. In the first stage there is a capillary congestion, the larger vessels not being involved to any extent, though the retinal veins are usually full. Later, a pale, slightly wasted appearance of the temporal side of the nerve will be observed, and if the vicious habit is persisted in, the whole of the optic disk becomes more or less pale and atrophied. Bull, quoting Romiée, says that the nerve fibres undergo fatty degeneration, accompanied by an increase of connective tissue. Noyes considers that "the pathological lesion is atrophy following inflammation of axial fibres of the nerve."

The ophthalmoscopic appearances are not always a correct index as to the degree of vision in these cases. Even where very slight atrophic changes have taken place, the vision may be greatly impaired.

Case II. is an example selected from numerous cases of amaurosis occurring in chronic alcoholism. M. D. M——, aged forty-three, Alpena, came to consult me in December, 1887. On examination, media clear, optic nerves showed capillary congestion on nasal half of disk, while the temporal side of disk showed beginning atrophy. Retinal veins enlarged but not tortuous. Vision in right eye $= \frac{1}{10}$, in left eye $\frac{1}{10}$. The central scotoma was here quite apparent, for these types could not be seen in central portion of the field. Of course, with such poor vision it was useless to test the color sense. He gave a history of long and free use of whiskey, and the moderate use of tobacco, with the exception of a few months when under the care of another physician, some eight months before he consulted me. The diagnosis was amaurosis from excessive use of alcohol, and treatment was begun accordingly. Free doses of potassium iodide, with bitter tonics, were given for about three weeks, and hypodermic injections of the nitrate of strychnia were given daily, beginning with one-sixteenth of a grain and increasing the dose gradually to one-fifth, and sometimes to one-fourth of a grain. Total abstinence from both alcohol and tobacco were rigidly enforced, and in order to accomplish this it was necessary to put the patient in hospital under

guard. Improvement went on rapidly. At the end of three weeks the potassium iodide was discontinued and galvanism was administered daily, and the strychnia injections were continued. At the end of seven weeks the general appearance of the patient was greatly improved, the optic disks looked more healthy and had lost much of the capillary congestion observed on nasal half of disk when first examined. Vision had increased in a remarkable degree, being $\frac{2}{5}\frac{0}{0}$ in right eye, and $\frac{2}{5}\frac{0}{0}$ full in left eye. For the near test, Jaeger, No. 1, could be read easily. For a year after dismissal the patient remained well, and, so far as known, his eyesight remained good. This patient had been treated eight months previously for his amaurosis by the internal use of strychnia, etc. In the hypodermic administration of strychnia a dose should be given once, daily, sufficient to produce the fullest physiological effects of the drug.

In detachments of the retina I have used the muriate of pilocarpine in several cases. In a majority of these there was some improvement of vision. This was probably due to its beneficial effect in clearing up the cloudiness of the vitreous, which so frequently follows the retinal detachment. In the cases of long standing there was little or no improvement as far as the retinal detachment itself was concerned. I now never use it in such cases. In cases of recent detachment of the retina, however, the hypodermic use of pilocarpine is well worthy a trial, as the following case will show:

Case III.—Miss A. C——, aged twenty-seven, came to consult me September 9, 1889, complaining of great loss of sight in right eye. She said she had a persistent sensation as if something were waving or floating in front of her. Ophthalmoscopic examination revealed an extensive detachment of the retina from the temporal side, which caused the sensations described. She was highly myopic. Vision equalled the ability to count fingers at a distance of between one and two feet in the central field; but upon turning the head so that rays of light fell upon the nasal side of retina, vision was much better.

Upon careful inquiry it was learned that, two weeks before, she was thrown from a carriage, striking on right side of head and shoulder. The failure of vision was gradual at first, but it had failed greatly for two or three days previous to consultation. The hypodermic use of pilocarpine was begun at once. The dose administered daily was increased gradually from one-twelfth to one-fourth of a grain. The latter dose produced free perspiration and flowing of saliva, with disturbance of the heart, giddiness, and sense of weakness. The injections were continued daily for about five weeks. At the end of that time vision had increased to $\frac{1}{1}\frac{6}{0}\frac{}{5}$. Ophthalmoscopic examination at this time showed almost complete restoration of the retina. Vision in the right eye had always been poor, and even in the uninjured eye it was only $\frac{1}{6}\frac{6}{0}$ with correcting glass.

Landesberg, of Philadelphia, and others, report gratifying results from the hypodermic use of pilocarpine in intra-ocular hemorrhage, opacities of the aqueous and vitreous humors, in choroiditis and detachment of the retina.

My own experience with hypodermic injections of pilocarpine in choroiditis and vitreous opacities has not been large. Neither have I been so successful in its use as Landesberg and some others.

Case IV.—Mary B——, aged thirty-two, is a fair example of the few cases in which I have used it hypodermically. This patient had disseminated choroiditis, with some cloudiness of the vitreous. She had been vigorously treated by another physician, who had given her protoiodide of mercury, the iodide of potash, mercurial inunctions, employed local blood-letting, etc. Vision in right eye $= \frac{2}{1}\frac{0}{6}\frac{}{5}$, and in left vision $= \frac{2}{1}\frac{0}{0}$. Injections of pilocarpine were not well borne, and only one sixth of a grain was given once daily. In four weeks vision was $\frac{2}{1}\frac{0}{0}\frac{}{0}$ in right eye, and $\frac{2}{4}\frac{0}{0}$ in left. The vitreous had cleared up considerably, retinal congestion had diminished, but there was no appreciable change in the choroidal spots. Improvement did not continue, and the injections were stopped two weeks later.

During the past few years the treatment of constitutional syphilis by hypodermic injections of mercury has attracted considerable attention. The various salts of mercury, as well as the metal itself, have been employed in this manner; and, as might be suspected, each particular preparation has its own advocates. I have not seen reports of any cases where the hypodermic injections of mercury were administered in syphilitic affections of the eye; but it is probable such cases have been reported. In the general treatment of syphilis it has been administered hypodermically in all stages of the disease and in a variety of ways.

Lang injects forty-eight grains of metallic mercury at two points during the same visit, and selects the back as the best point for the insertion. He mixes the mercury with lanolin and olive oil. He does not repeat the dose until after a lapse of from five to eight days.

Bender prefers calomel suspended in oil for hypodermic use. Hoffman found abscess to follow five times after ninety-six injections of calomel.

Wilander advocates the hypodermic use of calomel and other insoluble salts of mercury, but admits that he has seen abscess follow their use. Others prefer the albuminate of mercury, some the perchloride, others again the mercuric cyanide.

My own experience with the hypodermic use of mercurials in the treatment of syphilitic affections of the eye extends over a period of between four and five years. About four years ago I exhibited before this society some cases in which the hypodermic use of mercury had been employed with marked success.

I have experimented with several salts of mercury, but mainly with the sublimate, the albuminate, the salicylate, and the mercuric cyanide. The sublimate is irritating to most patients, and the albuminate and salicylate are not sufficiently soluble. The cyanide I have found the most satisfactory. Of this I inject daily about one fifth to one-fourth of a grain, beginning with a smaller dose. My experience with hypodermic medication has been confined mainly to its use in ophthalmic practice. I have treated thus a considerable number of patients exhibiting a variety of affections occurring both in secondary and tertiary periods. These have embraced diseases of the optic nerve and retina, paralysis of the ocular muscles, inflammations of the uveal tract—including the iris, ciliary body, and choroid—vitreous humor, and also gummy tumors of the iris, with iritis, etc. In the majority of these cases other remedies or modes of treatment had been tried by others or by myself, so that it was an easy matter to make comparisons as to the effectiveness of the hypodermic injections. In only one case did the hypodermic method prove less effective than others, and that was a case of iritis. In one case of choroiditis the improvement was as great as, but no greater than, when remedies were administered by the mouth. In all other cases the hypodermic medication proved itself superior to any and all others. It should be stated, however, that local treatment was also given in many of these cases; for example, in all cases of iritis and irido-cyclitis, atropia, hyoscine, etc., were freely employed, and in many other cases other remedies were administered when indicated.

The following cases are cited as illustrations of the facts here given:

Case V.—Mrs. S. E——, aged thirty-five, was brought to me, September 9, 1886. She gave a history of having contracted syphilis three years before. Although she had received treatment with mercurials and iodide of potash for the major portion of that time, she developed an unusual number of syphilitic lesions, such as papillary and squamous syphilides, sore-throat, falling out of the hair, iritis, etc. Seven months before consulting me she began to suffer from attacks of vertigo, nausea, and vomiting. A month later she had a paralytic stroke. The left arm and the left side of the face were paralyzed, from

which she had nearly recovered. Three months later she began to experience difficulty in co-ordinating her movements, which difficulty continued to date of examination. The patient was unable to stand or walk unaided.

In the right eye, old pupillary membrane from iritis, paralysis of external rectus muscle. In the left eye, complete paralysis of all the muscles except the superior oblique. Optic neuritis in left eye, which probably also existed in right, but on account of the pupillary obstruction no satisfactory ophthalmoscopic examination could be made. Memory and intellect were also somewhat impaired.

Treatment with large doses of iodide of potash was begun, together with mercurial inunctions at bedtime. Patient made slight improvement, but the iodide of potash produced such distressing symptoms that it was necessary to abandon it. The mercurial inunctions were ordered continued night and morning, with but little apparent benefit. Having had good results from hypodermic injections of mercury in previous cases, I began their use in this case. The beneficial effects were soon made manifest. The salt employed was the perchloride of mercury, and the beginning dose was one-twelfth of a grain, which was increased to one-fifth of a grain. Improvement, both in the condition of the eyes and the general condition, went steadily and rapidly on. At the end of four weeks after the first injection the optic neuritis was almost entirely cured, and the muscular control of the left eyeball had in part returned. The paralysis of the sixth nerve of the right eye had disappeared, and the patient could walk quite well, although there was still some lack of co-ordinating power. The use of the faradic current to the eye muscles was begun, and the injections were continued. The patient improved daily, grew strong, and increased in weight, and the paralyzed eye muscles one by one regained their normal power, except the external rectus of the left eye, which remained a trifle weak, although it had been the first to show improvement, so much so that for several weeks the left eye squinted outward. With the exception of the slight defect in the external rectus muscle of the left eye referred to, the case terminated in complete recovery, and whereas she was unable to stand or walk alone at the beginning of treatment, she was eventually able to walk several miles without fatigue.

Case VI. *Irido cyclitis, with Gumma of the Iris and Ciliary Body.*—Mrs. C——, aged thirty-five, consulted me, March 12, 1889. She gave a history clearly syphilitic, and for this she had had long periods of treatment. Three months previously her left eye reddened up, and became painful, but the trouble soon subsided, leaving vision unimpaired. Seven weeks before I saw her her left eye again became congested, painful, and inflamed, and the attending physician called in a specialist, and the two physicians had her continuously under their care until I saw her. She presented the following conditions: Great emaciation and prostration—she seemed a physical wreck, and with difficulty could stand or walk alone. Left eye intensely congested, a large gumma half filled the anterior chamber, the origin of which was in the upper and outer quadrant of the iris. It involved the ciliary body, and there was distinct bulging in the ciliary region at that point. The eye was totally blind, and had been for some weeks. There was no perception of light. The diagnosis was syphilitic irido-cyclitis, with gummy tumor of the iris and ciliary body. Right eye was normal, but showed symptoms of sympathetic irritation. There was also extensive ulceration of the throat. To relieve the intense pain of her eye, she had taken morphine several times a day, and although it had some influence upon her pain, it produced great gastric disturbance. On this, as well as on other accounts, I decided to try the hypodermic injections of mercury, and until such time as the full dose, one-fourth grain, was given she was also to use inunctions of the oleate of mercury at bedtime. The inunctions were discontinued after a few days. The mercuric cyanide was injected daily, and the dose rapidly increased to one-fourth of a grain. Savory & Moore's pancreatic emulsion was ordered, with beef-essence, milk-punch, and a generally nutritious diet. Atropia and cocaine were dropped into the eye several times daily. The patient's general condition improved rapidly, and the pain in the eye became less intense. On the fourth day a large portion of the gumma sloughed off, and seemingly filled the anterior chamber with a dirty, yellowish-gray mass. This quickly underwent absorption, and the gumma diminished rapidly.

On March 28th, sixteen days after the first visit, she had almost completely recovered from the severe irido-cyclitis and the gumma had entirely disappeared. At intervals, now, the hypodermic injections were suspended for one, two, or three days at a time, when she complained of stiffness or soreness of the muscles. During such periods she was given the iodides in small doses, or, when the stomach did not tolerate the iodide, mercurial inunction was employed. At the end of a month, all signs of inflammation having disappeared from the eye, the hypodermic injections were discontinued. She was ordered small doses of the iodide of sodium, which were alternated with protoiodide of mercury pills, and occasionally all treatment was suspended for periods of two or three weeks at a time. Occlusion of the pupil having resulted from the severe inflammation, I deemed it advisable to make an iridectomy, for artificial pupil. On July 16th I made an upward iridectomy, which gave her very good vision. But my notes do not give the visual acuity.

Why were not other modes of medication used, it may be asked? Because they had been long and vigorously used before she came under my care, and the result was a most pitiable failure. The patient's eye was in imminent danger of being destroyed, and the most effective means at my disposal were absolutely demanded. In concluding the notes of this case, I would say that the tension of the eyeball was above normal until all signs of the gumma had disappeared. This I have found to be true in all cases of large gummy tumor involving the ciliary border of the iris.

Case VII.—A. M——, aged fifty-three, consulted me, in November, 1887, for an affection of his ear. At that time it was noticed that his eyes seemed weak and lachrymose, but as patient did not complain of his eyes nothing was said regarding them. February 4, 1888, he came complaining that his eyes troubled him, and that his sight was greatly impaired. On examination the following conditions were noted: Right eye, marked ciliary congestion, lachrymation, and dread of light; vitreous hazy and full of floating bodies. Left eye, intense ciliary congestion, profuse lachrymation, great pain and tenderness on pressure, pupil contracted and irresponsive to light, discoloration and congestion of the iris, with posterior synechia; vitreous cloudy and filled with floating bodies. No satisfactory view of the fundus could be obtained in either eye. Vision, right eye, $\frac{1}{\infty}$, and left eye vision = perception of shadows, barely. Diagnosis, irido-choroiditis, with hyalitis. The patient had suffered from several attacks of rheumatism, and while there was also evidence of syphilis, the eye trouble was thought to be rheumatic in origin. He had been previously treated for rheumatism, but never with satisfactory results. In addition to local treatment with atropia and cocaine, I ordered salicylate of soda, in fifteen-grain doses, to be taken steadily till the full physiological effects of the drug were produced. This was continued for four days. While the salicylate relieved his pain to some extent the results were far from satisfactory. A saturated solution of iodide of potash was then prescribed, of which the patient took twenty-five drops well diluted, three times a day, the dose to be increased to fifty drops three times daily. In addition to this, mercurial inunctions were ordered night and morning. On March 4th, twenty-nine days after beginning treatment, the eyes were practically in the same condition

as on date of first consultation, except that the pupils were widely dilated and the posterior synechiæ in left eye were broken up. There was no improvement in vision, the eyes remained red, but a little less painful. Hypodermic injection of the cyanide of mercury was then begun, and the dose, given once daily, was increased from one twelfth to one fourth of a grain.

March 7th.—Marked improvement in every respect.

March 10th.—Ciliary congestion greatly diminished and pain entirely gone.

March 20th.—Vision shows improvement for the first time.

March 27th.—External appearance of the eye perfectly normal, and no indication of any inflammatory trouble except upon ophthalmoscopic examination. Ophthalmoscope shows vitreous still cloudy, with many floating bodies. From this time on, vision improved steadily and rapidly until it became normal in the right eye, and $\frac{12}{100}$ in the left. The cloudiness of vitreous in left eye still remains. This patient was given about sixty injections. He was entirely cured of his rheumatism.

Case VIII. *Syphilitic Iritis.*—August Q——, aged fifty, consulted me January 11, 1889. For two or three days eyes have been irritable, which patient attributes to reading late at night. Some congestion of conjunctiva, especially of right eye. Pupils responsive to light. Vision $\frac{20}{20}$, or normal. After instilling a few drops of homatropia in right eye, the pupil dilated readily and *ad maximum*. Ophthalmoscope showed media clear, and slight retinal hyperæmia. Next day patient complained of lancinating pains in right eye. Atropia was instilled and the patient was directed to return next day. He did not return, however, for forty-eight hours.

January 14th.—Right eye showed ciliary congestion, pupil not responsive to light, and did not dilate readily under use of atropia. Protoiodide of mercury, one-fourth grain, three times daily, and also mercurial inunctions were ordered, also the free use of atropia.

January 16th.—Pupil contracted, despite the free use of atropia; aqueous humor cloudy, vision greatly impaired, and considerable pain.

January 17th.—Eye much worse. Pupil greatly contracted and filled with lymph, intense ciliary congestion, severe pain, no reflex from fundus of eye, and vision reduced to perception of shadows. Iodide of potash in large doses was substituted for the protoiodide of mercury, and the inunctions and atropia were continued, and leeches were applied to temple.

January 18th.—The patient passed a wretched, sleepless night, and feels much depressed over the loss of sight in right eye, which is now complete, there being no light-perception. Treatment continued without change.

January 20th.—Conditions remained the same. Hypodermic injections of the mercuric cyanide, one-fourth grain, were begun, and the iodides were discontinued.

January 23d.—Some improvement is manifest, less pain, and patient sees light.

January 26th.—Improvement well marked, aqueous humor less cloudy, lymph absorbing, and some red reflex from fundus of eye; patient can count fingers.

From this time on improvement was rapid. Within two weeks from this date nearly all evidences of the severe inflammation had disappeared, the injections were discontinued, and patient came irregularly. About this time he spent several hours, driving a horse and cutter, in a sharp wind, and the exposure brought on a slight relapse which yielded to treatment within two or three days. On February 15th he was dismissed cured, with vision $\frac{20}{20}$.

My experience with hypodermic medication in inherited specific keratitis has not been extensive, and my success with it has not been so flattering as in most other cases.

Case IX.—T. M——, aged eighteen, a strong, vigorous man, was referred to me by Dr. Chittick, and from the doctor a distinct syphilitic family history was obtained. Left eye, profuse lachrymation, cornea greatly infiltrated and vascular, great ciliary congestion, ciliary neuralgia, and vision reduced to perception of shadows. The disease was of several weeks' standing and during most of this time he received from another specialist treatment which consisted in the main of potassium iodide and locally atropia. I ordered atropia and hyoscine locally, and the iodides were given in large doses. There was little improvement for some weeks, and I began the hypodermic use of the mercuric cyanide. While the improvement was still slow, it was more satisfactory.

Early in August the right eye became affected, and grew slowly worse despite the treatment. On August 19th five leeches were applied to right temple. On September 14th both eyes greatly improved, the right one improving most rapidly. The hypodermic injections were now discontinued. The mydriatic was kept up, and at intervals the iodides or protoiodide of mercury pills were given. Improvement continued and patient regained a fair degree of vision. On April 14th I saw the patient, after a lapse of several months, he having spent a good portion of it in the South, and on examination vision in right eye with $-\frac{1.5}{20} = \frac{20}{40}$, and in left eye $= \frac{20}{70}$.

The advantages of hypodermic medication over other methods are probably due to several causes, and its use under proper limitations may be commended upon the following grounds:

First. The medicine does not escape through some natural channel before it has entered the circulation, as is so often the case when medicines are administered by the mouth.

Second. The dose can be regulated with greater accuracy, and the action of the drug is more certain.

Third. The full physiological effect can be gotten almost instantly because the remedy is more quickly diffused through the system, and with drugs like strychnine, pilocarpine, etc., this is most important.

Fourth. In some instances results can be obtained by the hypodermic method which cannot be obtained otherwise.

Fifth. I have never seen ptyalism follow the hypodermic use of mercury.

Sixth. When medicines are not well borne, or when they produce unpleasant symptoms, hypodermic medication in appropriate cases will meet every indication, and will often prove itself superior to other methods.

Progress of Medical Science.

Posture in the Treatment of Nocturnal Incontinence in Children.—Dr. van Tienhoven suggests that in this condition though the bladder acts normally through the day, it misbehaves at night. He believes that the vesical sphincter is not strong enough to keep back the urine which collects in the bladder in the early hours of the night and permits it to find its way into the prostatic portion of the urethra. The detrusor vesicæ is thus reflexly stimulated and the bladder emptied. In order to prevent the urine from running into the urethra in this way the children were made to sleep with the pelvis elevated. In this position the bladder is capable of holding a certain amount of urine before the liquid reaches the level of the urethral opening. The foot of the bed must be elevated so that the bed forms an angle of forty-five degrees with the horizontal. The children should be sent to bed with empty bladders, and should not take any liquid just before retiring. They sleep well in this position and do not complain. Fourteen cases were treated by this simple method only, and all were cured in a short time.—*Correspondenzblatt für Schweizer Aerzte.*

Nephrectomy of One-half of a Horseshoe Kidney.—Professor Socin records a case of a woman, aged forty-seven, who had suffered for thirty years with one of her

kidneys; pain, colic, and pyuria had all attacked her in turn. The swelling at the time of operation was as large as one's head. An incision was made on the outer border of the rectus, and the tumor was found with the colon in front of it and to its inner side. It was punctured, and after the fluid was let out the edges of the opening were stitched to the abdominal incision. About a week later, as it was evident that the opposite kidney was healthy, and at the patient's urgent request, abdominal nephrectomy was performed. During the course of the operation the kidney was found to be attached across the middle line to its fellow, and had to be severed from it with the cautery. The patient made a good recovery. Socin draws attention to the fact that this is the only recorded instance in which a successful result has been obtained in such a case.—*Beiträge zur Klinischen Chirurgie.*

The Heart Disorders of Climacteric Women.—According to Dr. Kirsch, in the climacteric period of a woman's life she frequently becomes subject to a series of heart disorders without having had any definite disease of the organ at any time previously. The author describes three distinct varieties. The first is paroxysmal tachycardia. This occurs in plethoric women aged from thirty-eight to forty-eight. The percentage of hæmoglobin ranges from 110 to 120, against 93, the normal hæmoglobin percentage. In the earlier period of the climacterium the women begin to complain of palpitation coming on without provocation or upon some slight exertion, lasting from a few minutes to a few days. The very annoying sensation of a heart beating with excessive rapidity and strength is associated with a feeling of fear or terror, constriction of the chest, throbbing of the carotids, violent pulsation of the abdominal aorta, flushes of heat, increased blood-pressure in the head, and severe headaches. In rarer cases there may be profound vertiginous symptoms and even syncope; the pulse is very rapid—120 to 150 or more—but is strong, full, and regular. The normal heart sounds are exaggerated, and there are often functional murmurs. The patient suffers from mental anxiety and nervous irritability; her sleep is disturbed by disagreeable dreams, and she becomes unfit for active work. On the other hand, there are no symptoms of dyspnœa or cardiac asthma, no albuminuria, and very rarely indeed œdema of the feet or other symptoms of impeded circulation. The disorder is a comparatively harmless one, and is due to a reflex excitation of the extracardiac accelerator nerves. The condition is best treated with mild purgatives, light diet, active exercise, and cold sponge baths.

The second variety of cardiac disorder is "weak heart." This is much rarer, but much more serious. It occurs in women who in earlier years suffered from chlorosis or anæmia, or who in later years have lost great quantities of blood. The heart's action is rapid but weak. The pulse is small, feeble, compressible, and irregular. The heart sounds are obscured, and at times accompanied by systolic murmurs. The women are asthmatic, and often attacked by angina pectoris. Symptoms of impeded circulation are manifest, such as œdema of the hands and feet, and albuminuria. The hæmoglobin percentage is below the normal. The third group of cardiac disorders occurring during the climacterium is due to the accumulation of fat in the pericardium and sub-pericardiac connective tissue. It is the result of the general tendency which climacteric women have to the deposit of fat throughout the body, but chiefly in the mesentery and omentum. The symptoms are principally dyspnœa and palpitation, which supervene upon rapid walking, stair climbing, stooping, eating, etc. Real asthmatic difficulty and night attacks are seldom observed. However, in women who from their earlier years have shown a tendency to the excessive deposit of fat throughout the body, the condition becomes more serious, and occasions considerable distress. Dyspnœa and palpitation are caused by the slightest exertion, and cardiac asthma is not unfrequent. Venous stasis occurs at various points, and the patient suffers from hæmorrhoids and varicose veins of the legs. Œdema of the feet and lungs, and albuminuria, are not long in making their appearance at this stage of the disease. However, by careful treatment, judicious regulation of the diet, and observance of the laws of hygiene, the patient may be tided over the dangers of this period even though the symptoms be grave.—*The Birmingham Medical Review.*

Some Sources of Error in Sounding for Stone.—In a recent lecture Mr. Buckston Browne said his first proposition was, that in cases where the prostate was enlarged, stones are often missed when the bladder is examined, because the sound has not reached the bladder, but is arrested in the prostatic urethra. He illustrated this by several examples, and expressed an opinion that in many cases where the bladder was found contracted and the sound could not be turned, the real truth was that the sound had never entered the bladder. Next he proved that many stones were missed because the post-prostatic pouch is not explored. It was shown that in certain cases it was very difficult to explore this pouch by means of instruments passed in by the urethra, and that in certain other cases it was impossible to do so, and that in these rare cases the only way to thoroughly search was by means of suprapubic incision into the bladder. Several interesting and important cases from the author's personal experience were cited in illustration. The sound described was of solid burnished steel, with a round, smooth handle, a shaft ten inches long and equal to No. 7 of the English scale, ending in a smooth, broad, flat beak, exactly like the end of a broad, flat-bladed lithotrite. The author asserted that the beak of this instrument allowed it to ride easily over the bar at the neck of the bladder, and that it was not caught in one or other prostatic sinus as the end of the ordinary sound was so prone to be, and that when in the bladder it slipped more easily than an ordinary sound under a projecting prostatic middle lobe, and so enabled the surgeon to thoroughly search that favorite habitat of a stone—the post prostatic pouch.—*Medical Press and Circular.*

Cardiac Disease Consequent on Malarial Fevers.—The effects of malarial fevers are in many points obscure, and the damage done to the heart has never been made the subject of sufficiently long and accurate study. Clinical observers has often noticed soft systolic murmurs, sometimes apical but more frequently basic, and pathologists have found various traces of myocarditis and endocarditis; but the correspondence between the symptoms and the lesions has been imperfectly traced. Dr. G. Rauziet has spent much trouble on the point during a mild epidemic of malarial fever which lasted for rather more than a year. He gives detailed accounts of his observation of seventeen cases, in all of which a systolic murmur accompanied the fever, but which were none of them fatal. In all of these there was good reason to believe that there had been no previous cardiac disease, and the symptom constantly found was a systolic murmur culminating at the apex with an occasional reduplication of the second sound at the base, and no propagation of the systolic murmur along the large arteries except in one case. From this the inference is drawn that there was functional mitral incompetence; and there was not enough congestion of the spleen, liver, or lungs to make it probable that this was primarily due to dilatation from backward pressure in the circulation. The toxic effect of malarial poison in many ways is seen to be paralyzing. Dr. Rauziet is inclined to put forward the hypothesis that it acts on the heart through the nerves, to a degree lessening its complete contraction. He admits that it is hardly possible to determine whether the action is on the muscle directly, or by way of the nervous system. — *Revue de Médecine.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, January 24, 1891.

THE INJECTION TREATMENT OF SYPHILIS.

THE injection of mercurial preparations either subcutaneously or into the muscles, about which so much has been written of late, especially in the German journals, has not as yet become a favorite method of treatment in this country. The number of mercurial salts available for this purpose continues to multiply, some observers giving preference to the soluble, others to the insoluble, preparations. Those which appear to be receiving most attention just now are hydrargyrum thymolicum or thymoloaceticum, alaninicum benzoatum, oxycyanatum, formamidatum, succinimidicum, and salicylicum. The salicylate has recently been reported upon favorably by several writers. Schadeck employs an emulsion made with mucilage of gum acacia and water, so that each dose will represent from five to seven and a half centigrammes. This he injects into the muscles of the gluteal region. The course consists of from eight to twelve injections, extending over from twenty to forty days.

Dr. Gold, of Odessa, also favors the salicylate. He claims to have treated nearly four hundred cases by subcutaneous injection of insoluble salts without producing a single abscess, and maintains that little pain attends the operation, and no poisonous effects follow.

Dr. Boer, of Berlin, has employed in thirty cases a one and a quarter per cent. solution of the oxycyanide. He makes a daily injection of the contents of a Pravaz syringe (one gramme) into the gluteal region or the back, and continues the treatment for thirty or forty days.

It appears that the antiseptic properties of the oxycyanide of mercury, compared with those of the bichloride, make a solution of from one to one and a half in a hundred of the former (according to different observers), equal one in a thousand of the latter. A one per cent. solution is recommended for hypodermic use in syphilis, and from six to eight such injections are considered a course. The benzoate is recommended in the following solution :

℞. Hg. benzoat.	0.30
Aq. dest.	40.
Sod. chl.	0.10

From fifteen to fifty injections are given, according to the severity of the case.

Of the thymol salt the following formula in syringeful dose (Pravaz) has been used with good results :

℞. Hydrarg. thymolo-acet	1.5
Muc. gummi arab	0.5
Aquæ dest.	20.

Löwenthal adds cocaine to prevent pain. Hydrargyrum succinimidicum has been used by Selenew in one per cent. solution in thirty-three cases. He finds the effects not very marked, but recommends it in mild syphilis, especially in women and children. Recurrences were noted in about eight and a half per cent. of cases treated. It will thus be seen that the physician who desires to employ injections in his practice, or who now and then encounters a case in which other methods of administering mercury are not practicable or expedient, has at his command a number of preparations from which to choose. The salicylate especially appears to be growing in favor, and doubtless the hypodermic syringe will come to be used more and more in this country in the exceptional and not easily controlled cases, rather than as a routine method superseding those now more in vogue.

LADIES AND ATHLETICS.

Exigua est virtus præstare silentia re fœminarum." There is no merit in keeping quiet about the ladies, and it ought to be announced with no uncertain voice that woman has gone into athletics. On January 15th the Ladies' Berkeley Athletic Club celebrated the first anniversary of its foundation. This delightful consummation was reached amid flowers, dumb-bells, music, horizontal bars, lovely gowns, pulleys, wands, health-lifts, and the innocuous ice-cream and bouillon. The joyful ceremony as much as publicly announced that Venus was turning away from Mars and horrid wars, and was setting her Cyprian cap for Apollo, god of health, music, and parlor gymnastics. And the world will approve the coquetry. The Ladies' Berkeley Athletic Club is, we are told, an organization of ladies of the smarter sort who have taken up physical culture, and have done it so successfully that within a year they have established a finely equipped club-house and gymnasium and secured a membership of several hundred. Such a success means a great deal, for it is but the beginning of a movement toward athletics for women which promises to spread throughout the country and eventually affect profoundly the physical status of American women. It has taken only ten years for modern athletics to become an essential part of manly culture and physical enjoyment. It may take longer to witness such a change among the gentler half of the race, but it is sure to come.

In 1854 Catherine Beecher wrote : "I shall be able to show that the majority of parents in this nation are systematically educating the rising generation to be feeble, deformed, homely, sickly, and miserable." "The children of this country are every year becoming less healthy and less good-looking." Those of us who, happily, married some of the children of that generation may not entirely agree with all that was said then ; but we are very sure that Miss Beecher, if alive in the coming decade, could not write as she did forty years ago.

The lady athlete is essentially a modern creation. The poetry, the history, or the philosophy of the past never

suggest such a thing. To the poet woman has been a lovely, languishing, anæmically phthisical creation who disappeared after marriage and maternity; to the historian she has been an uninteresting necessity to racial continuance and human progression; to the philosopher she has been a most bothersome item to the perfection of society and the solution of its hardest problems. No one has looked upon her as a possible athlete, as a creature of physical force and exuberant health, in whom supple limbs and strong muscles accompanied lovely form and happy temperament. "The soul of bliss is health," said the immortal Thomson—immortal if he said no more. For surely happiness is impossible to the sickly, the feeble, and the diseased.

We congratulate the Ladies' Athletic Club on its already attained success and its prospective path-breaking future. It is making history, and we trust, in later years, when the present athletic members are giving to their somewhat rheumatoid but still active limbs the rest, with flannels (*otium cum flaneha*), that belongs to advanced age, they will be able to look back with pride and satisfaction on the propaganda of feminine athleticism which began in the year of grace 1890.

PHYSICIANS' MUTUAL PROTECTIVE ASSOCIATIONS.

The project of organizing physicians' mutual protective associations, in order to prevent imposition by patients who will not pay their bills, seems attractive, but it is not without its disadvantages. We learn that the President of the Physicians' Protective Association of Sharpsburgh and Etna, Pa., has been sued for $10,000 damages. The complainant received a notice from the president of the association, stating that the physicians had organized themselves into an association to enable them to collect delinquent accounts. The plaintiff's account, it was added, was overdue, and unless he paid it or made satisfactory arrangements by July 1, 1890, his name would be placed on the list of delinquents, and medical attendance would be refused him. The plaintiff claims he was not indebted to the defendant at all, and therefore paid no attention to the bill received.

The case brings up some interesting legal questions. On the one hand, it seems just that physicians, like any other class of bread-winners, should have the right of refusing to do work for which they are not paid. On the other hand, the combining of individual physicians into a league for the purpose of preventing the non-paying patient from receiving any medical attendance, may be looked upon as something in the nature of a boycott. We believe, however, that a just interpretation of the facts would lead to a conclusion in favor of the physicians. For, as a matter of fact, the patient can get medical service as soon as he makes up his mind to pay for it. If he is unable to pay for it, he should go to the corporate medical charities of his town, or make an appeal to the humanity of the physician. He has no more right to expect medical service gratis than he has to expect his grocer's and butcher's supplies.

The case cited above, therefore, ought to turn simply upon the question whether the patient really received medical attendance.

AN INTERESTING REVIEW.

We have received a copy of the *Verulam Review*, a journal whose modest purpose is indicated on its title-page. "Πάντα δοκιμάζετε τὸ καλον κατέχετε," which, we take it, must mean "Prove all things, hold fast the good." The *Review* finds little difficulty in carrying out the first half of this injunction. It criticises Professor Michael Foster and modern physiology, showing the emptiness of the one and the inutility of the other; it points out the base motives which actuated the work of the Hyderabad Chloroform Commission, and discloses its unscientific and inconsequential results; it disposes of the late Dr. William Harvey in eight pages, and announces the withdrawal of the bacillus from the fields of scientific interest and investigation.

It gives us a new word, "scientistic," which to the Verulam mind is apparently a biting term for a wanton and wicked physiology. The *Verulam Review* gives us on its cover the interesting information that during the first three-quarters of the year 1890 there were four thousand three hundred and twenty-eight convictions for cruelty to animals in England and Wales. One was for beating and kicking a goose; one was for stoning a linnet; seven were for kicking pigs; four were for worrying cats, and thirteen were for overworking donkeys. There were none for chasing and killing foxes or hares.

The *Verulam Review* is a most refreshing publication; its contributions are not put under the ordinary restraints of reason, logic, and fact, or submitted to the soul-clogging restrictions which make our other "scientistic" exchanges so arid. The *Review* has about it that child like freshness and spontaneity, the breath of intellectual spring-time, which make it a most cheering and most amusing companion. We hope the editors will never destroy its charm and originality by striving to acquire knowledge: "Το καλον κατέχετε."

THE PROFESSIONS AND IDIOCY.

According to Mr. Galton, in the *Journal of Mental Science*, a study of the natality of the members of some of the largest scientific societies of London, shows that the legal profession presents the most eminent men and the fewest idiots. The medical profession comes next, and lastly the clergymen, who produce the smallest number of eminent men and the largest number of idiots and feeble-minded. The lawyers give origin to six times as many eminent men as the clergy. The clergy originate six times as many idiots as lawyers.

Such statistical deductions appear to us to be misleading and unscientific to the last degree. In the first place, the term "eminent" has a most elastic meaning. A lawyer, by reason of his profession, may achieve notoriety and "eminence," when intellectually he is far inferior to a physician who is comparatively obscure. The intellectual status of a man is not decided nowadays by his "eminence." As regards idiocy, those who are familiar with the causes of this condition know that the occupation of the father cannot possibly have more than a very slight influence. Nearly thirty per cent. of idiocy and imbecility is the result of accidents at the time of labor. Another considerable percentage is due to infective fevers and accidents after birth; still other cases

are due to fright or injury to the mother during pregnancy; while the direct hereditary influence comes quite as much from the mother as the father. Taken altogether, it must be concluded that the particular form of brain-work followed by the father can exercise but a minimum influence on the production of idiot or imbecile children. The implied conclusion, that ministerial labor has six times as great a tendency to produce idiots as legal labor, is sheer nonsense, the circulation of which we regret to see associated with the name of so ingenious and industrious a savant as Mr. Galton.

News of the Week.

Lay Comments on Koch.—*The Boston Medical and Surgical Journal* collects a number of clippings from the daily press containing interviews and comments on the Koch lymph. This is one of them: "Schenkelberger on Koch. The Doctor's a Genius and would Scorn False Colors. Tamed the Wild Bacillus, and is consequently no Chump—Dr. Schenkelberger was a School-fellow of the Famed Consumption Slugger, and Knows what he Talks about." A common fact noted is the surprising number of pupils and school-fellows that Koch has had. One paper puts the matter in a most impressive way to the commercial mind: "At present the whole scientific world, along with the common herd of mortals, is excited over the discovery of a specific for consumption by an eminent German physician, Dr. Koch. This doctor, during an experiment, discovered what he is pleased to term 'lymph,' a preparation which is said to be worth $1,300 a drop. An ounce vial of it, injected according to instructions, would be worth the surprising amount of $780,000. This 'lymph' is claimed to be a certain and sure cure for that dreaded of all diseases, consumption." The *Journal*: "Some cities are unwilling to be outdone by Koch himself, and we find the names of no less than eleven physicians whose claims to have discovered the same, or an equally good 'lymph,' have been considered worthy of publication, not including the host of announcements appearing in connection with advertisements."

Insanity in Criminal Cases.—A bill has been drafted and presented to the New York Legislature providing for a change in the law relating to insanity and crime. It provides that "whenever, upon the trial of any indictment for any capital offence, the jury shall acquit the defendant on the ground of insanity, such insanity shall be presumed to continue, and the court in which such acquittal shall be had shall make an order that the person so acquitted shall be confined in the State Lunatic Asylum for a period of not less than ten nor more than twenty years, and until it shall be proved, in the manner provided by law, that the defendant has been restored to sanity." The Governor is given pardoning power. The law as it now stands provides that when a jury acquits a prisoner on the ground of insanity "the court must thereupon, if the defendant be in custody, and they deem his discharge dangerous to the public peace or safety, order him to be committed to the State Lunatic Asylum until he becomes sane."

Two New Hypnotics, Trional and Tetronal, have recently been tested by Drs. Barth and Rumpel, of Hamburg. They proved to be of about equal value with sulphonal. In certain cases of nervous affections, however, where the last named failed, the two former had the desired effect, and therefore may find a field of usefulness in this direction. Injurious after-effects were not observed, and faintness, sleepiness, etc., were not complained of, as is sometimes the case with sulphonal. The dose of both trional and tetronal is between forty-five and sixty grains daily, given in single fifteen grain doses; the remedies are best administered early in the evening, finely powdered, and mixed with about six ounces of fluid.

The Village Doctor.—In *All The Year Round*, 1883, there is a description of the Shillingbury doctor, Mr. Frederick Goldingham, M.R.C.S. We fancy we could pick out a dozen of such doctors who are the friends, companions, advisers, of village populations, "who pass their lives with patience and cheerfulness, listening to the garrulous grumbling, the discontent—ay, to the ingratitude sometimes—of a set of uncouth peasants and narrow-minded country tradesmen." The sympathetic writer says: "Honors and decorations the doctor did not want, but had he hungered after them he would have found they were not meant for such men as himself. These we keep for successful schemers in what is called the world of politics; for victors over hordes of half-naked, half-armed savages; and for the men who can pile up the largest heap of wealth by methods which we discreetly disdain to investigate. Our age is one which lets such noble deeds sink unmarked out of remembrance."—*Providence Medical Journal.*

A Conversation Partly Overheard at any Time between Two Physicians.—*First Doctor:* "—— Koch —— lupus —— lymph ——injection —— phthisis —— wonderful —— Koch." *Second Doctor:* "—— Extraordinary —— Koch —— lymph —— reaction —— phthisis —— Koch —— lupus —— remarkable —— bacilli —— Koch —— good-by."

The Surgical Section of the Academy of Medicine.—Dr. William T. Bull has been elected Chairman of the Section for the ensuing year. This is one of the most active of the several divisions of the Academy. The large attendance at the meetings attests the excellence of the papers presented.

Few Fractures of Patella in Philadelphia.—Two well-known surgeons, one from Philadelphia, the other from New York, were recently talking on their surgical work, when the Philadelphian said: "How happens it that you have so many fractures of the patella in New York? You are discussing the subject all of the time. I have had a fairly extensive surgical experience, yet have seen very few cases of this lesion." The New Yorker replied: "Your people in Philadelphia are too slow; if they would hurry a little, now and then, they might slip, occasionally, and break a patella."

Association Members in Illinois.—In connection with the question of removing the *Journal of the American Medical Association* to Washington, it is interesting to learn that Chicago and Illinois, with their two thousand physicians, contribute only five hundred members to the Association.

New York State Medical Association, Fifth District Branch, Brooklyn.—The Seventh Annual Meeting will be held in Brooklyn on Tuesday, May 26, 1891. All Fellows desiring to read papers will please notify the Secretary, E. H. Squibb, M.D., Brooklyn.

Alumni Association of the Woman's Hospital in the State of New York.—The Seventh Annual Meeting was held January 19, 1891. At the morning session, at ten o'clock, a new operation for the cure of anteflexion was performed at the hospital, by E. C. Dudley, M.D.; also a new method of suturing the perineum, by Clement Cleveland, M.D. At 1.30 P.M., luncheon was served by invitation of the President of the Association, Dr. Clement Cleveland, at the Academy of Medicine. During the afternoon session, at three o'clock, at the Academy of Medicine, the following was the order of exercises: 1. An Original Poem, by William H. Birckhead, M.D. 2. "An Undescribed Disease—Posterior Rectocele," by George E. Abbott, M.D. 3. "Uterine Hemorrhage of Obscure Origin," by H. C. Coe, M.D. 4. "Sterility in the Multipara," by J. D. Emmet, M.D. 5. "The Origin of Flap splitting in Vaginal Surgery," by A. H. Buckmaster, M.D. 6. "Recto-abdominal Fistula following Laparotomy, treated satisfactorily by Improved Double-current Irrigation," by Nathan G. Bozeman, M.D. 7. "Our Operating-rooms and Methods of Preparing Patients," by Le Roy Broun, M.D.

A Lymph Specialist.—The following advertisement was cut from the columns of one of the leading daily newspapers of Germany: "Dr. Koch's Cure. A lady, a friend of the great Berlin doctor, experienced with tuberculosis, will take four ladies to Berlin. Special advantages secured. Nurse attends. Doctors kindly notice."

A New Remedy for Constipation.—Dr. Platau, of Berlin, suggests a remedy for inveterate constipation, which, if it proves as satisfactory in other hands as it is claimed to have been in his own, will become a formidable rival of the popular treatment *à la glycerine*. It consists in the introduction of a pinch of powdered boracic acid into the rectum, preferably by insufflation, and the results are declared to be excellent, even in severe cases in which mechanical measures had signally failed to afford relief. The query rises, Who does the insufflation?

Projected Removal of the Journal of the American Medical Association to Washington.—At the recent meeting of the Board of Trustees in Washington, to consider this subject, many were in favor of immediate removal, while others deemed it a matter of such moment as to require careful consideration, and that the views of the entire Association should be had. The responsibility for such action, therefore, will devolve upon the membership of the Association as a whole at the next annual meeting.

The Mortality of New York City in 1890.—The total deaths in the city of New York during the year just closed were 40,230, a slight increase over the total of 1889, which was 39,583, as well as that of 1888, which was 40,175. The population being estimated at 1,631,230, the rate of mortality is found to be 24.6 to the thousand, as against 25.1 in 1889, when the population was held to be 1,580,000. A most marked falling off in scarlet fever is recorded, the deaths in 1890 being 403, in 1889, 1,239, the number of cases being 2,893 and 8,730, respectively. In diphtheria, also, there was a decline, the deaths in 1890 being 1,256, in 1889 1,685; the cases, 4,142 and 6,289, respectively. Typhoid fever caused 350 deaths, a decrease of 47; the number of cases was 1,079, a decrease of 296. Measles caused 724 deaths, an increase of 254; the number of cases was 8,972, an increase of 2,635. Whooping-cough showed a falling off—namely, 486 as compared with 647 deaths. The deaths by malarial causes were only 174, as compared with 229 in 1889. Small-pox caused two deaths, as against one in 1889. The deaths by bronchitis and pneumonia numbered 1,982 and 4,950, as compared with 1,792 and 4,015 in 1889. Consumption is charged with the heaviest item of mortality, 5,468, as against 5,163 in the previous year. The reported births came quite close to the deaths, being 39,250, a decided increase beyond the total of 37,521 in 1889. The marriages numbered 14,992, while in 1889 they were 14,400.

The Penis Percussion Reflex is a symptom confidently recommended to clinicians by Dr. C. H. Hughes, as of value in diagnosis and prognosis (*Scientist and Neurologist*). "If," says the doctor, "you take a perfectly healthy individual, whose spinal cord is entirely normal, especially in its genito-spinal centre, and place him on a couch without head-rest, supine, and nude about the loins, and make the sheath of the penis tense by clasping the foreskin with the left index-finger and thumb at about the place of the frænum, and pulling it firmly toward the umbilicus, placing the middle, ring, and little finger low down upon the dorsum of the virile organ, for perceptive purposes, and then sharply percuss the dorsum or sides of the penis, near the perineal extremity, a quick and very sensible reflex motor response or retraction of the bulbo-cavernous portion will be felt to result from this sudden percussional impression, like that which follows, though less pronounced, in the testicles, after sensory irritation of the inner aspect of the thighs, and known as the cremasteric reflex." Dr. Hughes thinks the presence or absence of the reflex indicates to some extent the virility of the individual.

Disadvantages of Large Hospitals.—Sir Morell Mackenzie objects to large hospitals, on the ground that they are an unscientific anachronism; the aggregation of the sick in large numbers being as much out of place as intramural interment. The added virulence of germs from the bodies of numerous cases is to be considered more dangerous than that of those emanating from dead bodies. Another objection to the large hospital is that the relief given by it is in a sense indiscriminate. The out-patient department of hospitals is the greatest pauperizing agency now existent. From this comes the third objection, the cruel hardships entailed upon the medical men in the neighborhood. He considers the special hospital in a large degree free from these and other objections, and favors the exaction of a small fee from dispensary patients.

Room for Another Medical Journal.—The *North Carolina Medical Journal* has made a discovery. It is that there is room for another medical journal. This should be devoted entirely to criticism and modelled after *The Dial* (save the mark!) or the *Literary World*.

THE LYMPH TREATMENT IN NEW YORK.

CASES AT THE ST. JOSEPH'S ORPHAN ASYLUM.

Service of Dr. Edmund Charles Wendt.

General Remarks.—No new cases have received inoculations during the past week. Thirteen of the old cases have been reinoculated, but in no case has the dose exceeded 0.008 gm. Some of the children still react rather violently, but in most instances the subjective symptoms are less severe, and the rise in temperature less marked. In order to ascertain the range of temperature when not influenced by lymph, the inoculations were interrupted for three successive days. In every instance (excepting two subnormal temperatures) the diurnal temperatures remained absolutely normal. Meantime, the children take cod-liver oil, are supplied with an abundance of good food, and receive such further symptomatic and adjuvant treatment as the exigencies of the individual cases appear to call for.

It is worthy of being recorded that all cases regarded merely as "suspicious," and even those with only scrofulous manifestations, have "reacted" to the lymph treatment. This naturally suggests the query, whether scrofula is not an early symptom of actual, rather than potential, tuberculosis.

One thing has been made quite evident to me, namely, that even though we are injecting a powerful poison, the general condition of strumous children improves under lymph treatment. There is much less anæmia at present. The extreme pallor of some of the cases is no longer perceptible. A few, indeed, are beginning to have an almost healthy look. The appetite suffers during the acme of the febrile reaction, but this passed, a marked change for the better has ensued. Children that had to be coaxed to eat, now demand food between meals. I cannot believe that a psychical element enters into this apparent amelioration, for the children only realize that something is "stuck into them," which hurts and makes them feel sick enough to go to bed. I may remark in this connection that I have given up using the abdomen as a place for injection. The sight of the syringe provokes resistance and struggling on the part of many children. Injections between the shoulder-blades seem to be less painful, and the child is not terrorized by seeing the syringe.

A surprising phenomenon to me has been the *va et vient* of auscultatory sounds. Some children quickly developed thoracic sounds simulating broncho-pneumonic foci scattered over a wide area. Yet they would be almost free from râles in from thirty-six to forty-eight hours. But under renewed inoculations a return of the râles was observed I shall not attempt here to explain these shifting signs, and merely wish to call attention to their occurrence.

Another point that has struck me in a peculiar manner is the absence of expectoration in children old enough to "raise phlegm," who had mucous râles not distinguishable from the bronchitic variety.

Without wishing to generalize, it appears to me that, while Koch has told us the origin of his lymph, we have yet much to learn with regard to the intimate nature of its surprising effects on the human body. Whatever the final outcome of the lymph treatment may be from a curative point of view, the reaction doctrine, if proven to be reliable, must give us a test of far greater importance than all the combined methods of physical and chemical exploration hitherto known. By its aid we should be able to give certain interpretation to those variable premonitory symptoms of phthisis that, with the means now at our command, permit no positive diagnosis. By its aid we would begin active treatment (not necessarily with lymph), even before the microscope revealed to us, by bacilli-laden sputum, that the danger-point was near.

Particular references to single cases are omitted in this week's report.

CASES AT ST. FRANCIS HOSPITAL.

Service of Dr. George F. Shrady.

(Reported by Arthur P. Coll, M.D., House Surgeon.)

During the past month thirty patients have been treated for tuberculosis with the Koch lymph. Three of these were tuberculous joint cases, two of knee, and one of wrist; two were of tuberculous glands of the neck, two were of scrofulous ulceration with tubercular caries, the remainder having phthisis pulmonalis. Of the latter there were three control cases, which failing to react were discharged. In all the others the reactions occurred according to rule, most of them showing local reaction in the shape of increased râles and expectoration. In two cases of incipient phthisis the expectoration markedly diminished, and in one of them the physical signs also disappeared, the patient believing himself well.

One of the cases of tubercular knee-joint progressed in rather a remarkable way. At the commencement of treatment by inoculation the joint was tender on pressure and movement, and there was considerable contraction of the flexor muscles of the thigh. These symptoms gradually disappeared after repeated inoculations with reactions, so that at the end of a month the patient was able to straighten the limb and walk about the ward with a slight limp. The pyriform swelling of the parts remained. The patient, protesting that he was well, left the hospital to return to his home in Germany. The case appeared, according to the usual tests, to be one of the ordinary tubercular joint, and the facts are stated without any attempt to explain an apparent relation of cause and effect.

The second case of knee-joint disease, still under treatment, has shown a curious improvement. The patient is a female who had been treated for tubercular disease of the part for a period of many weeks, the limb being confined in plaster of Paris and other appliances during most of the time. Associated with the joint lesion was a deposit in the lung and the expectoration of tubercle bacilli. Reactions occurred after each inoculation. The patient is now able to walk around the ward without pain and without crutches. A wrist-joint similarly affected showed similar improvement.

The cases of phthisis are progressing in the usual way, none of them under treatment as yet ceasing to show the reactions. All express themselves as feeling better, but no perceptible increase of weight is noticed, although the majority of them have increased appetites.

The frequency of inoculations has been governed by the effects produced, care being taken to differentiate between the usual hectic fever and the increased temperature of the reactions by allowing a sufficient interval to elapse for a return of normal temperature. In one or two cases with cavities it has been impossible to note more than an increase of the hectic following the inoculations. These are the simple facts in the cases reported, without any attempt at theory or explanation.

Boracic Acid in the Treatment of Tuberculosis.—Dr. Gaucher, writing in the *Bulletin Médical*, speaks highly of the action of boracic acid in cases of pulmonary tuberculosis. In cases so treated the author notes a marked diminution in the amount of expectoration, which also becomes more fluid and less purulent. In a number of cases submitted to this treatment, and kept under observation for five years, there had been no progress in the pulmonary lesions, and the general condition of the patients had improved. At first he gave but fifteen grains of the acid a day, but of late he had gradually increased this dose to one drachm daily, with apparent benefit. The drug possesses the advantage of being tasteless, and produces no gastric irritation. In certain cases it seemed to exert a beneficial effect upon the diarrhœa.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, November 21, 1890.

BEVERLEY ROBINSON, M.D., PRESIDENT PRO TEM.

The Finger as a Medium for Transplanting Skin Flaps.—DR. GEORGE F. SHRADY read a paper in which was described a new method of transplanting flaps from one part of the body to the other by using the finger as a medium. The case on which the operation was demonstrated was that of a young woman whose cheek was restored by that means. The operation consisted in placing the arms in an easily folded position over the epigastrium, so that the palms rested upon the corresponding elbows anteriorly. A quadrilateral flap was then dissected from the lower and anterior portion of the arm, so that the free edge of the flap could adapt itself to the radial margin of the forefinger in position below it. This free edge was sewed to the radial side of the forefinger, the skin of which latter had been previously split for the purpose. The forearms were then confined in plaster of Paris until union between the arm-flap and finger had taken place. The arm-flap was then detached at its base, leaving the entire flap still attached to the finger. The hand was then placed against the face, and the free end of the finger-flap sewed in position to the upper margin of the cheek gap. Immobility in this position was also maintained by plaster of Paris until union between finger-flap and cheek was complete, when the finger was liberated, leaving the original arm-flap as the new cheek.

This new cheek throve well throughout its entire extent for a period of two months, at the end of which time, its lower portion being necessarily disturbed by an operation for a sliding flap to remedy neighboring defects, a slough of its lower and superficial portion occurred, fortunately leaving, permanently, enough of the original flap to prove the practical utility of the measure.

In connection with these operations upon the patient, Dr. Shrady described others which he had previously performed on her for the purpose of closing up the gap in her cheek. Twice he converted her mouth, including upper and lower lips, into a quadrilateral sliding flap, the free edge of which was sewed to the outer border of the cheek gap, thus temporarily closing the latter. In each instance the deflected mouth was properly righted by closing it at one corner and enlarging it at the other, thus making its median line correspond with that of the face. These efforts were only partially successful, owing to the difficulty of obtaining firm union between sound skin and a dense bed of cicatricial tissue in the cheek proper.

To remedy other defects various other operations were performed, in all amounting to twenty-two, the patient confidingly following the operator from one hospital to another during a period of three years. At the end the patient was left with a reconstructed face, from which, at the end of four years, most of the scars had faded away. The new cheek, although somewhat thinner than the one on the opposite side, is reasonably supple, and obligingly wrinkles to balance the smile of satisfaction on the other side of her face whenever the results of the operation are referred to.

Dr. Shrady believed that this method could be applied to the transplantation of flaps to and from even distant parts of the body within reach of the hand.

At the close of his paper Dr. Shrady remarked that the last operation was performed on this patient four years ago. Before, she wore a veil and would go out only after dark. Since the series of operations her appearance had improved very markedly, although there was still slight deformity at the angle of the mouth, which she desired him to remedy by a further operation. Thinking it was best to let well enough alone, he had declined to do this.

He further added that the patient developed a marked tolerance for ether after several operations had been performed, and would require an unusual length of time to go under the influence of the anæsthetic. He then made use of Nussbaum's method of hypodermic injection of morphine before ether was administered.

DR. C. L. DANA inquired whether after the operations there was any wrong reference of sensory impressions.

DR. SHRADY replied in the negative. In answer to a question from Dr. Bull he also remarked that the method adopted in this case of transferring the mouth was new to him; at least he did not know that it had ever been done before. It involved a good deal of hemorrhage, but was the only available way at that stage of covering the large space left by a slough in the cheek.

DR. W. T. BULL thought the author had described a form of flap transplantation which was likely to offer advantages over any hitherto in vogue.

Regarding Anæsthetics.—Dr. Bull could endorse what the author had said with regard to mixed narcosis. He had never employed a combination of chloroform by inhalation and morphine hypodermically. The combination had consisted of ether by inhalation and morphine by injection, the latter administered after, not before, ether inhalation. The patient being fully anæsthetized by the ether, an injection of from two to ten minims of Magendie's solution would prove of great value in plastic operations about the face. He had had no experience in covering so large a defect as that described in the paper, and he knew of no other method by which as marked success could have been obtained.

DR. J. D. BRYANT said that he, like those who had already spoken, had been able to continue an operation much longer after bringing the patient under the influence of ether, by then adding a hypodermic injection of five or seven drops of Magendie's solution. Less frequently he made the injection at the beginning of ether inhalation. He asked Dr. Shrady whether he had also employed whiskey.

DR. SHRADY replied, not as a rule, for he thought it had a tendency to disturb the stomach when administered by the mouth. It was of advantage hypodermically when the patient was very weak.

DR. SAMUEL SEXTON said that he had used a mixture which had been mentioned in a discussion on anæsthetics some years ago. It consisted of one part by measure of alcohol, two of chloroform, and three of ether. He had employed it in his last twenty or twenty-five operations on the ear, and it had proved quite satisfactory; the patients had become anæsthetized readily and came from under the influence very nicely. He could recall but one case in which there was any vomiting. Usually not over half an ounce was inhaled before the patient came under the influence.

Congenital Median Furrow of the Nose.—DR. W. T. BULL presented photographs of a peculiar case of congenital median furrow in the tip of the nose, existing in a prepossessing young lady, who requested an operation for cosmetic effects. Two sittings were required, the procedure adopted consisting in dissecting out the furrow and bringing the edges of the wound together. The result had been satisfactory. Replying to a question by Dr. Shrady, he said there was no harelip or other deformity.

Salivary Calculus.—Dr Bull further presented a salivary calculus, which he said was the first he had ever removed. The patient, a man about thirty years of age, had an attack of sore throat and cold in the head, about six years ago, which was accompanied by some swelling in the submaxillary region. Every ten days or so since that date he had observed a little swelling beneath the submaxillary gland, which he would relieve by pressure on the neck outside, causing a quantity of mucus to discharge into the mouth. A few days ago he caught cold, there was acute swelling in the gland, apparently the submaxillary, which nearly subsided by the end of a week under hot

fomentations. When Dr. Bull examined him he detected a hard body at the floor of the mouth, and with the aid of a little cocaine anæsthesia made an incision on the line of Wharton's duct, and extracted a hard calculus. It had not yet been examined as to its chemical composition.

Dr. Shrady said he had met with a similar case. The gentleman had come on from Pennsylvania to have his tongue extirpated for supposed cancer. On examination Dr. Shrady found a tumor of considerable size under the tongue, and on introducing an exploring needle struck something hard. While the patient was yet sitting in his chair, he made an incision and removed a salivary calculus nearly as large as the end of a man's thumb. It had interfered somewhat with deglutition and speech.

One Disadvantage of Litholaplaxy.—Dr. Bull also presented the fragments of a large vesical calculus in a case which illustrated one of the disadvantages of litholaplaxy. The fragments presented weighed altogether seven hundred and twenty-five grains, and were composed of phosphates. A year before, the man had been operated upon by litholaplaxy by one of the best known specialists in the city, the stone which was crushed being so large as almost to fill the bladder. The patient, however, began to have bladder symptoms again about two months after the first operation. He had an enlarged prostate, and the third lobe was removed by supra pubic operation at the time when the stone was also extracted. Notwithstanding phosphatic stones were known to form sometimes very rapidly, Dr. Bull confessed to some astonishment on finding so large a one in this case, in which litholaplaxy had been performed only a year before. He added that the removal of the prostate had not overcome the symptoms of obstruction. During the same week that he had operated upon this patient he had encountered another one, who had been operated upon by litholaplaxy three months before, by the same surgeon; yet, at this early period he again had two new vesical calculi—unless, indeed, they were old ones which had been left. The two cases served to strengthen the opinion which he had already formed, that litholaplaxy was a somewhat unsatisfactory operation, because one could not always be sure of having extracted all the calculus material. It was particularly undesirable in old people who had obstructive disease of the prostate, and were obliged to use a catheter.

Dr. Bryant endorsed the position taken by Dr. Bull by citing the following case: A man, forty-seven years of age, had stone in the bladder, for which he operated five days ago. He also had enlargement of the prostate, and had for many years suffered from renal calculi, but believed that all had passed up to a certain date, when his prostatic symptoms also developed. His physician also recognized the fact that, for about ten years, his patient had been suffering from enlargement of the prostate. When Dr. Bryant selected supra-pubic cystotomy in preference to litholaplaxy in this case, it was partly from the standpoint advanced by Dr. Bull. Believing that litholaplaxy was quite likely to be attended by inability to remove all the fragments, especially on account of enlargement of the prostate, and believing that the nucleus of the calculus had probably been retained only since the development of prostatic obstruction, he chose the supra-pubic operation. The operation was attended by no difficulty; the highest temperature reached was on the next day, 100.8° F. The man having considerable adipose, the opening was rather extensive, but was healing kindly, it now being the fifth day. The objection to litholaplaxy which Dr. Bull had advanced was, he thought, a sound one, and had actuated him in this case, but he did not understand that Dr. Bull did not believe in litholaplaxy al all.

Dr. Bull said he had been understood correctly by Dr. Bryant.

Dr. Beverley Robinson asked whether one of his patients, aged twenty-five, on whom he could not pass an instrument of fair size, might have enlargement of the prostate without disease.

Dr Bryant said he had seen a man, aged thirty-five, have marked enlargement of the prostate, and there were records of enlargement at a much younger age, but they were very rare.

To Preserve the Elasticity of the Lungs—Dr. J. West Roosevelt presented a specimen of prepared lungs, which he had exhibited at the recent International Medical Congress, where it had excited a good deal of interest as something new. The method and the result had impressed him as something useful rather than as new. The lung had been prepared a year ago, and had retained its physical characteristics up to the present, as could be demonstrated by inflating it with a rubber bulb. The objection to filling the lung with glycerine and carbolic acid was that it became stiffened and disagreeable to handle, and, moreover, was apt to shrink in places. It therefore occurred to him to inflate the lung, fill it with Flemming's fixing solution, then saturate with glycerine and carbolic acid to get rid of everything, and displace these with an oil which contained some of one of the essential oils. The specimen had remained elastic a year, and by continuous inflation with the rubber bulb enabled one to study the vesicular murmur.

Dr. Roosevelt also exhibited some drawings of the terminals of the bronchi.

A Set of Electrodes for Use in Rhinology and Laryngology.—Dr. Robinson exhibited a case of electrodes which he had devised for use in diseases of the nose and throat. With them was a universal handle. They were made by Stemmer. He expressed incidentally his belief that many cases of so-called globus hystericus were due to a third tonsil. The question of removal of the tonsil arising, he said the operation was more or less bloody, and while not considered dangerous, he preferred to avoid the necessity for it where he could by use of the electrodes.

THE NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 12, 1890.

J. West Roosevelt, M.D., President, in the Chair.

Cerebellar Hemorrhage with Complete Paralysis on the same Side as the Lesion.—Dr. J. S. Thacher presented such a specimen, showing a hemorrhage of considerable size in the left cerebellar hemisphere, and a minute lesion in the opposite hemisphere. The patient had suddenly become comatose, and on his recovery a few hours later, was found to have paralysis of the left extremities. After about one week without any especial change in the symptoms, he again became comatose, and died. References in medical literature to the occurrence of hemiplegia upon the same side as the lesion in these cases were very vague. Gowers makes the obscure statement, that paralysis occurs on the same side, or upon the opposite side, according as the pressure is upon the pons or upon the medulla. Probably the correct inference is that, if the pressure be upon the pons, the paralysis is on the same side as the lesion. Dr. Thacher thought that an explanation might be found in the fact that direct pressure was made by a soft and diffused body, while the counter-pressure upon the beginning of the crus cerebri, on the opposite side, was by the sharp, firm anterior edge of the opening of the tentorium cerebelli. This latter might have a greater effect in producing a lesion of the pyramidal tract.

Dr. H. P. Loomis presented the lower portion of a tibia in which the process of necrosis had resulted in a complete and extensive separation of the old bone, and the development of new bone from the inner layers of the periosteum. The specimen was taken from a man, about twenty-nine years of age, who had been in perfect health up to about two months previous, when after a day's work upon his knees, was seized with severe pain in

one knee. After one week, pus was evacuated from an opening made into the knee-joint, and very soon the lower portion of the leg was riddled with sinuses. Amputation at the knee was performed. The specimen showed that recovery would have been impossible without operative interference.

Dr. Loomis also presented specimens illustrating

Primary Tuberculosis of the Genito-urinary Tract.—They were removed from a woman about forty-five years of age, whose history was unknown. There was considerable pus in the pelves of the kidneys, and some concretions. The bladder showed, in addition to cystitis and thickening of its walls, the usual appearance of tuberculosis of this organ. The cervix and body of the uterus and the vagina showed small ulcerations, which were in all probability tubercular, although stained sections had not shown the presence of tubercle bacilli. The other viscera were normal with the exception of the heart, which was sufficiently diseased to account for the patient's death.

The PRESIDENT remarked that he had seen apparent tuberculosis of the uterus, Fallopian tubes, and both kidneys, without any involvement of the bladder. Tubercular disease of the testicle and kidney was also common enough; yet the course followed by the tubercle bacilli in gaining entrance to the genito urinary tract was not known.

DR. L. EMMET HOLT presented specimens from a case of tuberculosis in a child four and a half years of age. The family history was negative so far as tuberculosis was concerned. One year ago, the first signs of Pott's disease in the lower cervical region were noticed, and deformity had been present for about two months. Five months ago, enlargement of the cervical and axillary glands was first noticed. During the past summer, with the exception of frequent headache, she had been in fair condition up to two weeks before death. Then she was suddenly seized with vomiting, the headache became more severe, and there was constipation with moderate fever.

Nine days later, she was admitted to the hospital. At this time she was very drowsy, but could be partly roused; slight opisthotonos; cervical and axillary lymphatics enlarged to the size of a hen's egg; and nodular tumors about the size of an almond could be felt along the spine through the abdominal wall. There were localized fine râles at the right apex of the lung; spleen slightly enlarged. During the next five days, the temperature ranged from 100° to 101°; there was occasional vomiting, constipation, steadily increasing drowsiness, and, during the last two days, irregular pulse, irregular respiration, and convulsions, first affecting the left side of the face, then both upper extremities. There was also almost complete left hemiplegia. Pupils were dilated, and there was convergent strabismus. Abdomen was natural until the last twelve hours, when it became greatly distended. Death occurred in convulsions with a temperature of 104.5° F.

At the autopsy, the brain was found slightly congested; the pia closely studded with miliary tubercles at the base, along the Sylvian fissures, and particularly over the choroid plexus. Tubercles were also scattered over the convexity, but very little pus or fibrin was to be seen anywhere. The ventricles were not distended. The sinuses contained dark fluid blood. The cord was not examined. The bronchial glands and all the mediastinal glands were all very greatly enlarged, forming a cluster about the trachea and large bronchi nearly as large as the fist, individual glands being from one-half to one and a half inch in diameter, and cheesy on section. At the right apex, a small area of consolidation, studded with tubercles the lung rather firmly adherent over this area. In other portions of the lungs there were scattered miliary tubercles; no areas of consolidation, and no pleurisy. The heart was normal. The liver was fatty and somewhat adherent to the diaphragm, and a few tubercles were found on its surface and in its substance. The spleen was increased to about twice its normal size, and showed tubercles on its surface only. The kidneys were soft and slightly enlarged, showing throughout a moderate amount of parenchymatous nephritis, and in one, a tubercular nodule about the size of a pea, which had broken down. The stomach contained a tarry mucus, and showed many minute follicular ulcers, about the size of a pin's head. A few small tuberculous ulcers were found near the ileo-cæcal valve. About the cæcum, vermiform, and sigmoid flexure was a localized plastic peritonitis. The mesenteric and retro-peritoneal glands were everywhere enlarged and cheesy, the average size being one to one and a half inch. The case was one of general tuberculosis involving chiefly the lymphatic system, and followed by a tubercular meningitis.

Dr. Holt also presented specimens from a child aged ten months, who had been admitted to hospital four days before death with a history of marasmus since birth. Her weight was six and three-quarter pounds, and during her stay in the hospital there was no temperature, cough, or evidence of any local disease. Physical examination showed the body greatly emaciated, and at the left apex was a small area of consolidation giving dulness, bronchial breathing, and fine râles. The lungs elsewhere, together with the other organs of the body, were normal. The child died suddenly, having appeared two hours before death as well as at any time for the past four days. At the autopsy, the examination of the brain and heart was negative. The lungs showed a consolidation involving the greater part of the left upper lobe, and on section the lung showed numerous small cavities communicating with each other. A few large cheesy nodules had not yet broken down. The pleura over the lung was normal. Throughout the lower lobe of the left lung were small reddish nodules as large as a small pea, the centres evidently of infection by aspiration from the disease in the upper lobe. Miliary tubercles were scattered throughout both lungs. The bronchial glands upon the left side were cheesy, but not broken. There were no ulcers in the small intestine, but a partly cicatrized ulcer was found in the rectum, about four inches from the anus. A few cheesy mesenteric glands occupied the right iliac fossa. Scattered tubercles were seen upon the surface of the liver, but the spleen only showed two or three on its surface. The kidneys and peritoneum were normal.

THE PRESIDENT exhibited a metallic cast showing the ramifications of the bronchi. It was of interest in connection with Dr. Holt's second case, as it showed how easily the tubercular material could be distributed through the lung by aspiration.

The Society then went into executive session.

The Vienna Professor as a Humanitarian—"I assure you this hospital is for the benefit of science, not for the sick. It will be many, many years before patients can be handled in America as they are here, and I doubt very capitally if we will ever live to see the day. Why, when one of these professors says an operation must be done, the patients never think of opening their mouths: they are led up just like sheep, as meek as Moses, trembling, scared half out of their wits, yet they don't open their mouths at anything. The patients will bear any sort of pain; why, I have seen them amputate the thumb of a six months' old babe without any form of an anæsthetic; scrape away the whole of a man's nose with a curette, and then with the actual cautery completely cauterize; and when an American would ask the professor why he didn't cocainize the part or anæsthetize the patient, he would say in the presence of the patient that he didn't have time to anæsthetize him, and it costs too much to buy the cocaine, also saying that it would be best to use something to alleviate the pain in private practice; just as if it didn't hurt the poor suffering hospital patients."—*Vienna Correspondence of Dixie Doctor.*

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

DR. CHAMPNEYS'S HARVEIAN LECTURES—BONE IN THE BLADDER—KOCH'S TREATMENT—A NEW UTOPIA—THE ADDENDUM TO THE PHARMACOPŒIA—NEW-YEAR'S HONORS FOR MEDICAL MEN—SIR RICHARD QUAIN, BART.—SIR GEORGE HUMPHRY—MR. WALLACE AND SURGEON PARKE ON THE VALUE OF VACCINATION.

London, December 6, 1890.

In Dr. Champneys's second Harveian Lecture he discussed the subject of "Membranous Dysmenorrhœa." Pathological study, he said, had not settled its nature, and its clinical study had been too much neglected. He believed that it threw considerable light on spasmodic dysmenorrhœa. Dr. Champneys described the membrane which was passed in such cases, and discussed the method proposed by Wyder of diagnosing it from membranes which were the products of conception by means of the large cells said to be present in the decidua but absent from dysmenorrhœal membranes. A typical case was then described, and it was pointed out that it was essentially a primary affection. The flow was profuse—at any rate, not scanty—and the pain was not relieved by the flow, though it was relieved by the passage of the membrane. Such patients were usually sterile and menstruation was generally painful until it ceased at the menopause. The disorder sometimes ran in families. The lecturer regarded the pain as a "colic" intensified, being set up by the passage of the membrane over a specially sensitive part. He remarked that in cases of membranous dysmenorrhœa we must distinguish the membrane from fibrin, blood-clot, coagulated mucus, casts of the vagina or bladder, exfoliation of uterine mucous membrane (in cases of phosphorus poisoning and cholera), foreign bodies, and, lastly, from products of conception. The latter included: (*a*) Decidua in cases of extra-uterine pregnancy, (*b*) decidua in cases of double uterus, (*c*) abortions.

The third and concluding lecture (delivered on December 4th) was devoted to the consideration of "Spasmodic Dysmenorrhœa." Dr. Champneys claimed that this was the only real dysmenorrhœa. The following terms were employed in its nomenclature: Spasmodic, neuralgic, obstructive, mechanical. This form was essentially primary. The pain typically preceded the flow and was relieved by it; it was situated in the womb, and might, with intermissions and variations in intensity, last from twenty-four to forty-eight hours. The flow was scanty in such cases. As a rule, the affection got worse with time. The "mechanical theory" of this form assumed that it might be due to flexion, to stenosis, or to chronic congestion produced by flexion. With regard to flexion we had the evidence afforded by the difficulty of passing the sound in such cases, the evidence of specimens of flexed uteri, and the illustration of bent tubes. In support of stenosis being an efficient cause we had the cases of congenital stenosis with "pinhole os;" Vedeler's statistics on this point were quoted, together with some cases under the lecturer's own observation. We had also to consider the effects of swelling of mucous membrane, the presence of fibroids or polypi, contortion of the cervical canal from hypertrophy, and increased flow of blood. With respect to flexion being set up by chronic congestion of the uterine organs, we had to consider the circulation in the uterus. Were flexions essentially associated with dysmenorrhœa? The statistics of Vedeler and Herman on this point were given. Arguments in favor of such association had been derived from the results of some forms of treatment, viz., postural treatment, treatment by means of vaginal or stem pessaries, dilatation, and incision.

At the last meeting of the Clinical Society an interesting case was brought forward by Mr. Buckston Browne, viz., one in which he had removed several fragments of bone from the bladder of a male patient in whom disease of the spine had existed for several years. The pieces of bone were shown to the Society and the history of the patient related. Mr. Browne remarked that bone might obtain entrance into the bladder by mechanical violence, or by the slower processes of disease. Bone had been removed from the bladder after long standing hip-joint disease.

Ischio-rectal abscesses had been opened and fragments of bone discharged therefrom in cases where the abscess was due to Pott's disease of the spine. Dr. Walshe and others had published cases where pieces of bone had been coughed up from the lungs, after spinal abscess resulting from injury to the back. The late Mr. A. Shaw had recorded a case where a spinal abscess had discharged itself into the bladder, but Mr. Browne said he was not aware of any case on record where bone from the spine had been discharged into, or had required removal from, the urinary bladder. When an operator had any reason to believe (when performing lithotrity) that he had to do with bone or a bony nucleus, it would be desirable to proceed with great caution, for it would be exceedingly easy for the lithotrite to become so entangled with a piece of bone that its jaws could not be disengaged, nor the bone (owing to its toughness) crushed, and then cystotomy would have to be performed under unfavorable conditions. Mr. Browne remarked that among the foreign bodies he had found in the bladder were a pair of forcipressure forceps (which had found their way there from the peritoneum, where they had been left during an abdominal section some months before), and the silk ligature of an ovarian pedicle.

Koch's new method of treatment for tuberculosis and lupus continues to be the foremost subject of interest in medical circles. Sir Joseph Lister has returned from Berlin and gave an address on the subject at King's College Hospital a few days since. His impressions were favorable to the remedy. He regarded its action on tubercular disease as simply astounding, both as a curative and a diagnostic agent. He did not himself think that it was impossible for the dead portions of tissue resulting from the treatment to be got rid of by other than surgical means. Provided they were preserved from septic agency they need not necessarily be separated from the living body, as they could, he thought, be absorbed in the same manner as a catgut ligature was. Sir Joseph Lister compared the action of Koch's fluid with that used by Pasteur in the case of anthrax, an injection of which gave complete immunity from the disease, and said he hoped Koch's future researches would result in showing the remedy capable of so acting on human beings as to give them complete immunity from tuberculosis.

Sir Joseph Lister then briefly alluded to some further researches now being carried on under Koch's superintendence, and said that though he was not at liberty to mention any details, he saw, in the case of two of the most virulent infectious diseases to which man is liable, that the injection under the skin of an inorganic chemical substance cut short these two diseases. The animals were rendered incapable of taking the diseases under the test of the most potent inoculations.

In view of such discoveries as these, it is scarcely extravagant to argue that we may in time realize the conditions of existence depicted in one of Walter Besant's romances ("The Inner House"). In that work a physician discovers an elixir which will prolong life indefinitely (barring deaths from accident), and it is universally adopted amid unbounded enthusiasm. Mortals, in short, are described as already immortal, and death as banished from the community except as the result of violence—accidental or otherwise. In Besant's work, however, as the race advances physically, it retrogrades morally and intellectually, so that after some ages some of the less

degenerate determine to emigrate, and, perhaps, give up the use of the elixir.

In the addendum to the Pharmacopœia, antipyrin, nitro-glycerine, saccharin, and lanoline are designated as follows, respectively, viz.: Phenazone, trinitrin, glnside, and adeps lanel hydrosus. The reason for adopting fresh names is that the names first mentioned have been registered as trade-marks by certain manufacturing druggists, and can therefore only be used to specify the preparations as made by them. Obviously, the General Medical Council could not stamp as official the manufactures of certain druggists to the exclusion of others. Among the other articles added to the British Pharmacopœia will be found antifebrin and phenacetin. The advisability of the two latter additions will certainly be widely questioned.

London, January 2, 1891.

The New Year's honors given by the Crown comprise several for members of the medical profession. Dr. Richard Quain is made a baronet, and Professor Humphry, of Cambridge, is to receive the honor of knighthood, while minor distinctions are conferred on three medical men holding foreign appointments. Few will grudge Dr. Quain his baronetcy, though it comes rather late in life if it is intended as a reward for his long services to the profession, and those who have known him for half a century (Dr. Quain graduated at the University of London in 1840 as M.B., and proceeded to the M.D. degree in 1842) as Dr. Quain will find it difficult to learn to address him as Sir Richard Quain, Bart., now that he is entering his seventy fifth year. Dr. Quain was one of the earliest members of the staff of the Brompton Consumption Hospital, and was for many years an active worker at that fertile field of observation. A genial Irishman, he speedily became popular with patients, and has for many years past enjoyed a lucrative and increasing practice—not limited, however, to diseases of the chest. A Fellow of the Royal College of Physicians during the last forty years, he has long been one of the trusty advisers of his college, and, as such, took an active part in the establishment of the order of Licentiates—a step which has in due course led to the association with the sister college for the purpose of establishing the Conjoint Board. Dr. Quain has also been for years a member of the Senate of the University of London and of the General Medical Council, Physician Extraordinary to the Queen, and (by which he will perhaps be best remembered) the editor of the "Dictionary of Medicine" which bears his name.

Sir George Murray Humphry will live longest in memory as one of the virtual founders of the Cambridge Medical School. Himself an alumnus of St. Bartholomew's Hospital, London, he settled in Cambridge half a century ago, where he became surgeon to Addenbrooke's Hospital, graduating subsequently at the University of Cambridge. Dr. Humphry became in after years Professor of Anatomy (more lately of Surgery) at the University, and in that capacity was, during nearly a quarter of a century, untiring in his efforts to promote the success of the Cambridge Medical School. In this he was warmly seconded by others, notably by Sir George Paget (a brother of Sir James Paget), who is also a distinguished alumnus of the same university.

The Royal Commission on Vaccination have just issued a third report, which is largely made up of evidence from the opponents of vaccination. One of the most eminent of the witnesses who gave evidence adverse to the practice was Mr. Wallace, the distinguished naturalist. In reply to questions from Sir James Paget, Mr. Wallace said that he regarded the introduction of vaccination and the diminution of small-pox as what might be called a casual coincidence; he thought it reasonable to believe that the medical observers of that time were deceived, and that they were especially mistaken, and more than mistaken, in believing that vaccination acted for a whole lifetime. In concluding his evidence Mr. Wallace urged that vacciuation did not account for the diminution in the mortality from small pox, and that the facts on record could be accounted for independently of vaccination. He had laid before the Commission a diagram showing that the decrease of the small-pox mortality of London from 1800 to 1822 was far greater than could be attributed to the amount of vaccination then performed, and a decrease from 1822 to 1884 on the whole far less than it ought to have been from the great increase in the amount of vaccination. Diagrams of Sweden and Prussia showed very similar phenomena, while in Stockholm, Berlin, and Vienna modern epidemics had been as severe as those of the dreadfully insanitary London of the eighteenth century. Mr. Wallace laid great stress on the improvement in the sanitary condition of the population during the last century, as leading to a decrease of mortality from a number of diseases. The Prussian and Austrian armies, both vaccinated and revaccinated, showed an enormous difference in small-pox mortality, but there was a corresponding difference in the general mortality of the two nations, so that the facts were accounted for independently of vaccination. The incidence of small-pox on the vaccinated and unvaccinated was now approximately proportionate to the numbers of these two classes in the community, showing that vaccination had absolutely no effect in warding off attacks of small-pox; while the close agreement in the total percentage of small-pox mortality to cases in the last century, and since vaccination had been enforced, offered a strong presumption that it had not influenced the mortality from the disease. The advantage of the vaccinated over the unvaccinated depended upon a combination of circumstances which had often been pointed out, the unvaccinated including three distinct groups of individuals on whom the disease was likely to be especially fatal, viz.: (*a*) Infants under vaccination age; (*b*) all those in whom vaccination had been postponed on account of ill health or weakness; (*c*) all those who escaped the vaccination officers—a class including the nomad populations, who were living under the most insanitary conditions. Mr. Wallace said that from these facts he drew the conclusion that vaccination was absolutely powerless either in preventing attacks of small-pox or in diminishing small-pox mortality.

The evidence of Surgeon Parke, medical officer to the Emin Relief Expedition, was a refreshing contrast to the pessimistic attitude assumed by Mr. Wallace. Surgeon Parke's testimony was that vaccination was of great value as a protective against small pox. He believed that it saved the lives of many men attached to the expedition. Of the natives who had been vaccinated only four were attacked and none died; those who had not been vaccinated suffered terribly and numbers of them died. Tippoo Tib's men had confluent small pox in a terrible form.

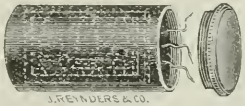
Bad Breath.—Dr. Frank H. Gardner gives the causes of bad breath as follows: First, decaying particles in the mouth as far back as the pharynx vault taint the breath, if exhaled, very little if at all. Second, mouth-breathers have a bad breath when the tonsils are enlarged, or when cheesy masses exist in the tonsillary mucous folds. Third, certain gastric derangements taint the breath only when gases are eructated through the mouth. Fourth, the principal cause of bad breath is decomposition in the intestinal canal, the retention of fecal matter in the transverse and descending colon, and the absorption of gases into the circulation, finally exhaled by the lungs. Fifth, catarrh—nasal, pharyngeal, or bronchial—causes bad breath. Sixth, medicines or ailments which undergo chemical changes below the œsophagus may, by rapid absorption through the stomach walls, or immediately below, give to the breath the characteristic odor. Bad breath is often a source of serious annoyance to the patient, and the fact that it has more than a local cause is too often ignored by the physician, who therefore fails to cure it.—*Dental Review.*

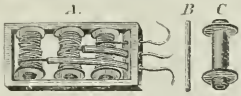
New Instruments.

A NEW LIGATURE BOX.

By F. E. SYLVESTER, M.D.,
NEW YORK.

In nearly every medical and surgical journal of the day we notice articles upon the use of catgut, and its uses for ligatures and sutures, while never a word in regard to the best and safest method of carrying and keeping it always at hand ready for use. If you visit the different hospitals in this and other cities you will notice nearly every operator has his ligatures wound upon glass tubes or cylinders, and thrown loosely into a bottle of antiseptic fluid for transportation, and when using must remove from bottles and unwind as thread from a spool. Many times the whole coil of "gut" becomes infected, either by the unclean hands of the assistant, or by coming in contact with septic material, viz., table, clothes of assistant, etc., and the next time the surgeon operates he finds his wound suppurates, through the infection caused by infected ligatures, and condemns the gut, when the unhandy and unsafe method of carrying his ligatures is responsible for the condition. Others buy their ligatures prepared for the trade by irresponsible people. We are not sure the gut is properly prepared, or that the solution in which it is immersed is safe for us to use from.





The bottles used by the trade are mostly of the old style of glass jars, with glass rollers containing the ligature, with a soft rubber cork, perforated for the gut to pass out, at top, and over this a metal cap, screwing down on top of bottle. The objection to this class of case is, that in nearly every instance, after the cap is once removed, dirt lodges on top of the rubber cork, and at second time of using we find that our ligatures have become infected.

After trying nearly all the prepared articles of gut ligatures I found that to be sure of having a ligature I could depend upon for strength and safety I must prepare my own; and then arose the question how to carry it to be handy for emergency and general use and at the same time embrace all the antiseptic qualities the surgeon of to-day looks for when wishing an article for surgical use.

After some time spent in trying different articles on the market, without finding just what I wanted, with the assistance of William Harz, of J. Reynders & Co., I devised a case large enough to carry three spools of different sized ligature, each spool large enough to hold four to six yards of gut, according to size, still small enough to fit a pocket found in nearly all obstetrical bags.

The case is made of hard rubber, in form of a cylinder, four inches in height, with solid bottom, and cover screwing down on inside of case, making it fluid-tight (see cut). The spools (*C*) are placed in a frame cut from one piece of rubber, turning on a movable shaft (*B*), so in refilling they can be removed from the frame and the ligature wound on as thread upon a spool and replaced. To avoid the entangling of one strand with another, there are placed two small rubber tubes at top of frame, extending down to upper border of second and third rollers (*A*), the ligature from first roller passing directly through slot in frame. The whole frame containing gut is then placed in the cylinder and covered with the fluid preferred, the frame fitting closely enough to retain itself in position when traction is made in using. This has been perfectly satisfactory in every detail, and can be sold at such a price that all who wish to use an article of this kind can well afford one.

230 East Thirty-Second Street.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 11, 1891, to January 17, 1891.

Snyder, Henry D., First Lieutenant and Assistant Surgeon. By direction of the Secretary of War, relieved from duty at Fort Reno, Oklahoma Ter., and will report in person to the Commanding Officer at Camp Guthrie, Oklahoma, Ter., for duty at that station, relieving Captain John L. Phillips, Assistant Surgeon. S. O. 11, par. 16, A. G. O., Washington, D. C., January 14, 1891.

Phillips, John L., Captain and Assistant Surgeon. By direction of the Secretary of War, on being relieved will report in person to the Commanding Officer at Fort Reno, Oklahoma Ter., for duty at that station. S. O. 11, par. 16, A. G. O., Washington, D. C., January 14, 1891.

Harris, Henry S. T., Assistant Surgeon. To be Assistant Surgeon with the rank of Captain, after five years' service, in accordance with the Act of June 23, 1874, January 5, 1891. A. G. O., Washington, D. C., January 12, 1891.

Wood, Leonard, Assistant Surgeon. To be Assistant Surgeon with the rank of Captain, after five years' service, in accordance with the Act of June 23, 1874, January 5, 1891. A. G. O., Washington, D. C., January 12, 1891.

Official List of Changes in the Medical Corps of the United States Navy for the week ending January 17, 1891.

Hord, W. T., Medical Director. Ordered as President of Medical Board, to relieve Medical Director J. Y. Taylor.

Dean, R. C., Medical Director. Detached from Hospital, Chelsea, and ordered to Medical Board, Washington, D. C.

Taylor, J. Y., Medical Director. To be placed on the retired list, January 22d.

Rush, W. H., Passed Assistant Surgeon. Orders to the Newark are revoked.

Asheridge, Richard, Passed Assistant Surgeon Orders to the Saratoga revoked, and wait orders.

Cabell, A. G., Passed Assistant Surgeon. Detached from iron-clads and ordered to the Newark.

Lumsden, G. P., Passed Assistant Surgeon. Ordered to the iron-clads at Richmond, Va.

The Size of the Fœtus.—Anvard states that the length of the fœtus at different ages is about as follows: At the middle of the fourth month it is eight inches in length; at the middle of the fifth month, ten inches; of the sixth month, twelve inches; of the seventh month, fourteen inches; of the eighth month, sixteen; of the ninth month, eighteen; and at the end of nine months it is twenty inches long.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 17, 1891.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	7	3
Scarlet fever	135	12
Cerebro-spinal meningitis	1	2
Measles	413	18
Diphtheria	89	19
Small-pox	0	0
Varicella	14	0
Pertussis	4	0
Croup	3	0

Agricultural Colonies for the Chronic Insane.—The "Board for the establishment of State Insane Asylum Districts," have placed the following counties in the Hudson River State Hospital District: Washington, Rensselaer, Columbia, Dutchess, Putnam, and Westchester. This district has 1,159 insane, as stated by the Districting Board, while the hospital for the district has accommodations for 800 patients only. In their report to the Legislature for 1885, the managers mentioned fourteen counties as naturally belonging to the Hudson River State Hospital District. These counties were Westchester, Rockland, Putnam, Orange, Dutchess, Ulster, Greene, Columbia, Albany, Rensselaer, Schenectady, Richmond, Queens, and Suffolk. By the census of 1880 these counties were given a total population of 962,933. It was estimated that their insane in 1885 numbered about 3,400. The chief reasons for putting these counties in one district were their easy access to the hospital at Poughkeepsie by rail and river, and the low rates charged for transportation of passengers and freight. The managers have not changed their belief that the true interest of the River Counties can be best secured and served by a central hospital at Poughkeepsie.

Much has been said of the evils of contact with each other of large numbers of insane in the hospital ward, charged as it were with an atmosphere of insanity; of the morbid environment from which the patient has no escape, and which intensifies and multiplies his delusive ideas; and of the difficulty under these conditions of applying such special modifications of treatment as the individual peculiarities of each case might require.

It is not to be forgotten that questions of economical administration are mainly responsible for the system in vogue. It is true in one sense that the more patients in one building, the less the per capita cost of support; hence our massive buildings, constructed on a uniform plan throughout, too expensive for the needs of the large majority of patients, and not expensive enough—that is, not money enough expended—to make them properly adapted for the successful treatment of a small minority among the insane. It is believed that some of the evils complained of in the present system would disappear, or be notably lessened, if quiet and harmless patients were cared for under conditions more nearly allied to family life, having at the same time the constant oversight of the skilled physician.

It is believed that a large majority of the 3,400 insane belonging to the Hudson River Counties might be provided for in small buildings grouped in hamlet fashion; each group to accommodate 250 to 300 patients; each hamlet to be in the centre of a farm of several hundred acres, and to have its farm buildings and stock; also a building in which light mechanical work would furnish occupation in winter, and a small cottage hospital for such as needed its care; and in the centre of the group a residence for the physicians having the immediate care of the patients. The cottages would be homely, perhaps, but homelike and comfortable in their arrangements, and so disposed about the grounds and among the trees as to give a pleasing and picturesque effect. Occupation would be the key-note or motive of the hamlet life, and this in the open air and amid familiar rural scenes. The products of the soil would go far toward the maintenance of the establishment, and in time yield a surplus to be sold at a profit in the markets of New York City. Such agricultural colonies established from time to time, as necessity demanded, and scattered about among the beautiful hills and valleys lying just east of our present hospital, and all being under one central control and management, would furnish economical and adequate provision for housing and supporting the natural increase of the insane population, which is now adding annually more and more to the burden of taxation.

The State Commission in Lunacy report about 2,000 insane that must be removed from county asylums and poor-houses to State institutions, and that about 500 of this number can be transferred to existing State hospitals, leaving some 1,500 to be provided for in buildings yet to be erected by the State. On the first day of October, 1890, there were present at the Willard and Binghamton Hospitals 1,342 patients belonging to the Hudson River Counties. It would be a humane proceeding, and bring joy to hundreds of poor families, to transfer these patients to the Hudson River State Hospital, so that they might be in the neighborhood of their homes, and see and be seen by their friends once more. Such a transfer would leave 1,342 unoccupied beds at Willard and Binghamton, and so furnish accommodations at those hospitals for nearly all who require such accommodations in the counties lying west of the Hudson River Counties. That this plan would accomplish the purpose now in hand, of providing for all the pauper and indigent insane, we have high authority for asserting. It would be, moreover, in harmony with the provisions of Section 4, Chapter 126, Laws of 1890, and from this it follows, that the only new buildings really needed at this time are those that should be put up in connection with the Hudson River State Hospital, and its hamlet scheme.—*Extract from the Annual Report of the Managers of the Hudson River State Hospital, Poughkeepsie, N. Y.*

In Articulo Mortis.—No human being can rest for any time in a state of equilibrium, where the desire to live and that to depart just balance each other. If one has a house, which he has lived and always means to live in, he pleases himself with the thought of all the conveniences it offers him, and thinks little of its wants and imperfections. But once having made up his mind to move to a better, every incommodity starts out upon him, until the very ground-plan of it seems to have changed in his mind; and his thoughts and affections, each one of them packing up his little bundle of circumstances, have quitted their several chambers and nooks, and migrated to the new home, long before its apartments are ready to receive their bodily tenant. It is so with the body. Most persons have died before they expire—died to all earthly longings, so that the last breath is only, as it were, the locking of the door of the already deserted mansion. The fact of the tranquillity with which the great majority of dying persons await this locking of those gates of life, through which its any angels have been going and coming from the moment of the first cry, is familiar to those who have been often called upon to witness the last period of life. Almost always there is a preparation made by Nature for unearthing a soul, just as on a smaller scale there is for the removal of a milk-tooth. The roots which hold human life to earth are absorbed before it is lifted from its place. Some of the dying are weary and want rest, the idea which is almost inseparable in the universal mind from death. Some are in pain, and want to be rid of it, even though the anodyne be dropped, as in the legend, from the sword of the Death-Angel. Some are strong in faith and hope, so that, as they draw

near the next world, they would fain hurry, as the caravan moves faster over the sands when the foremost travellers send word along the file that water is in sight. Though each little party that follows in a foot-track of its own will have it that the water to which others think they are hastening is a mirage, not the less has it been true in all ages and for human beings of all creeds which recognized a future, that those who have fallen, worn out by their march through the desert, have dreamed at last of a river of Life, and thought they heard its murmurs as they lay dying.—Oliver Wendell Holmes.

Curious Food.—The lion is eaten by some African races, but its flesh is held in small esteem. The Zulus find carrion so much to their liking that, according to the late Bishop Colenso, they apply to food peopled by large colonies of larvæ the expressive word "uborni," signifying in their uncouth jargon "great happiness." David Livingstone, that keen and accurate observer, reminds us that the aboriginal Australians and Hottentots prefer the intestines of animals. "It is curious," he says, "that this is the part which animals always begin with, and it is the first choice of our men." On this point I may remind the civilized reader that the woodcock and the red mullet, or sea woodcock, are both eaten and relished without undergoing all the cleansing processes which most animals used for food among us generally experience to fit them for the table, so that our aversion to the entrails of animals is not absolute, but only one of degree. The hippopotamus is a favorite dish with some Africans when they can get this unwieldy and formidable river monster, and when young its flesh is good and palatable, but with advancing years it becomes coarse and unpleasant. The Abyssinians, the amiable people to whom, according to the Italian Prime Minister, his countrymen proposed to teach wisdom and humanity, find the rhinoceros to their taste; so they do the elephant, which is also eaten in Sumatra. Dr. Livingstone describes the elephant's foot as delicious, and his praises will be echoed by many travellers in lands where that sagacious monster still lingers in rapidly decreasing numbers. "We had the foot," wrote the doctor, "cooked for breakfast next morning, and found it delicious. It is a whitish mass, slightly gelatinous, and sweet like marrow. A long march to prevent biliousness is a wise precaution after a meal of elephant's foot. Elephant's tongue and trunk are also good, and after long simmering much resemble the hump of a buffalo and the tongue of an ox, but all the other meat is tough, and from its peculiar flavor only to be eaten by a hungry man."—*Annals of Hygiene.*

Typhoid Bacilli in Urine.—Dr. Justin Karlinski communicates the results of some observations on the existence of typhoid bacilli in the kidney and urine. In six cases of typhoid fever the urine was taken after death by means of a trocar, and in thirty-eight cases it was drawn during life by a catheter and examined bacteriologically by means of gelatine plate cultures. In the cases where a post-mortem examination could be obtained sections of the kidney were also made, and examined by inoculating gelatine as well as microscopically by Konarieff's process. Of the six cases where the kidneys were obtained, collections of rounded granulation elements were found in five, both in the cortical part and beneath the capsule, a few typhoid bacilli lying among them. In the central portion no bacilli were found. In one case they were found in the tissue lining the pelvis of the kidney. In the forty-four cases in which the urine was examined Eberth's bacilli were found in twenty-one, all these specimens of urine containing also albumin. In cases where the albuminuria was transient the bacilli were not discovered. Sometimes they appeared in the urine much earlier than in the stools; the earliest appearance in the urine being on the third day, while they were never detected in the fæces before the ninth day of the disease. They were, moreover, much easier to find in the urine. Dr. Karlinski also made a series of experiments in order to ascertain whether these bacilli develop in albuminous urine. For this purpose he kept tubes of albuminous urine containing them for some time in a thermostat at about the temperature of the body and examined them daily, with the result that he found the number of colonies increase very rapidly. The vitality of these was preserved also for a long period. Experiments were likewise made with urine containing bile, but it was found that this entirely destroyed the bacilli in about five days.—*The Lancet.*

Painful Flat-foot (Valgus) and the Different Methods of Osteotomy which are Applicable for its Cure.—Dr. Kirmisson says that three theories have been advanced as to the origin of this condition: 1. Duchenne's muscular theory, involving the functional impotence of the lateral peroneus longus. 2. Gosselin's theory, that the disease is the result of primary lesions in the articular cartilages. 3. Le Fort and Tillaux's theory, that it is due to relaxation of the ligaments. Still another theory has been advanced, by Whitmann, that the lesions and deformities are the consequence of the overloading and overriding of the plantar vault. In the author's opinion the most important element is the turning of the foot outward, from which follow traction on the ligaments, pain, and functional impotence. The proof of this theory consists in the fact that when one succeeds in correcting the forced abduction of the foot, the latter, while resting on the level, ceases to give rise to pain, inasmuch as the weight of the body then rests upon the plantar surface of the foot and not upon its internal border. After having tried complete rest for the member in bed, which may be required after there has occurred a muscular contraction of average intensity, one must have recourse to forced redressment, aided by chloroform and tenotomy of the lateral peroneal muscles, as advised by Barwell. This should be followed by prolonged immobilization of the foot in a plaster bandage. If the results of such treatment should not be permanent, or if extreme muscular retraction or deformity of the articular surfaces do not favor redressment, osteotomy should be practised along the internal border of the foot. The best-known procedures are Bennet's cuneiform excision of the astragalus, Stokes's resection of the astragalus, Vogt's extirpation of the astragalus, Ogston's operation upon the astragalo-scaphoid articulation, and Davy's and Golding-Bird's operation upon the scaphoid. The author believes that osteotomy is only exceptionally indicated for this lesion.—*Archives of Pediatrics.*

A Surgical Use for Ants.—Ants have very powerful jaws, considering the size of their bodies, and, therefore, their method of fighting is by biting. They will bite one another, and hold on with a wonderful grip of the jaws, even after their legs have been bitten off by other ants. Sometimes six or eight ants will be clinging with a death-grip to one another, making a peculiar spectacle, some with a leg gone, and some with half the body gone. One singular fact is that the grip of an ant's jaw is retained even after the body has been bitten off and nothing but the head remains. This knowledge is possessed by a certain tribe of Indians in Brazil, who put the ants to a very peculiar use. When an Indian gets a gash cut in his hand, instead of having his hand sewed together, as physicians do in this country, he procures five or six large black ants, and holding their heads near the gash, they bring their jaws together in biting the flesh, and thus pull the two sides of the gash together. Then the Indian pinches off the bodies of the ants and leaves their heads clinging to the gash, which is held together until the gash is perfectly healed.

The Cost of the Johns Hopkins Hospital.—Up to two years ago, the buildings of this Hospital cost about two million dollars.

THE ETIOLOGY OF THE DISEASE KNOWN AS SUPPURATIVE TONSILLITIS AND ITS SURGICAL TREATMENT.

WITH REMARKS CONCERNING THE PREVENTION OF INFLAMMATORY DISORDERS OF THE TONSILS.[1]

BY CLARENCE C. RICE, M.D.,

PROFESSOR OF DISEASES OF THE NOSE AND THROAT, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, NEW YORK.

THERE is no further demand in medical literature for exhaustive treatises on inflammatory conditions of the tonsils. The subject of tonsillar inflammation has with the appearance of each new text-book been brought up to date.

If, however, we compare the notes on tonsillitis we wrote in our books when we were first or second year medical students with the descriptions of the disease which have been written within the year, we mark the striking similarity between the two as to classification of disease, etiology, and symptoms. The etiological division into predisposing and exciting causes has been followed, and the several factors under these two divisions have been formulated in about the same terms by writers during the past ten years.

There are two phases of this subject, however, which are at present receiving special attention, and which may, when better understood, change considerably the present accepted ideas of the etiology of tonsillar inflammation.

One is *the physiological functions of these organs*, and the other is the amount of truth which will be demonstrated to exist *as to the bacillary or septic causation of inflammations here and elsewhere.*

In stating the etiology of tonsillar inflammations, it makes some difference whether we believe that the tonsils simply give shape to the masses of food as they pass into the alimentary canal, and furnish lubricating fluid for the pharynx, or whether, as absorbents, they drink up superfluous fluid and digested products. It is an important point to be decided in arriving at the cause of the frequency of the several manifestations of tonsillar inflammation whether the tonsils are to be regarded as open-mouthed, unprotected viaducts through which each and every kind of pathological microbe may easily pass into the general lymphatic system, or whether, on the contrary, they are blood-fortifying reservoirs filled with leucocytes which stand as sentinels to destroy the micro-organisms which enter the commencement of the respiratory and alimentary tracts.

It cannot be denied that the location of these collections of lymphoid tissues, both the faucial tonsils and the adenoid tissue in the post-nasal pharynx, is most convenient for either of these purposes; and that they possess important physiological functions would seem most reasonable.

The different physiological actions which have been attributed to the tonsils by such investigators as Killian,[2] Spicer,[1] Hingston Fox,[2] Stöhr,[3] Schmidt,[4] and others all deserve consideration, because the conclusions arrived at are the result of painstaking observations.

Most investigators are agreed that the adenoid tissue situated at the vault of the pharynx called Lushcka's tonsil, the faucial tonsils, and the lingual tonsil are histologically indentical, and that they are similar to lymphatic tissue in other parts of the body. Another point, which seems to be a settled one, is that the tonsils, like other lymphatic tissue, are remarkable organs, in that they contain a multitude of leucocytes, and are in all probability blood-elaborating organs. Whether these leucocytes are only in a condition of immigration toward the general circulation to fortify the blood, or whether, in addition to this, they pass outward into the pharynx to attack micro-organisms which have entered the mouth, remains to be shown. It is easy to understand that the tonsils may possess either or both of these functions.

That the tonsils, like other lymphatic tissue, perform an important part in the elaboration of the blood seems to be proven by the following clinical observations:

First. The entire lymphatic tissue situated in the upper respiratory tract is largest during the formative period from infancy to puberty.

Second. That after that period, when it is not so much needed, this lymphoid tissue shows a strong tendency to atrophy.

Third. That in strumous, cachectic, unhealthy children, where the blood-producing organs are most needed, the tonsillar tissue, both in the post-nasal and middle pharynx, is more largely developed than in healthy children.

Fourth. That in cases of marked anæmia occurring in the young the functional tissue of the tonsils has been found to be deficient.

What shall we say to the objection that may properly be urged, viz., that strumous children, who have exceedingly large tonsils, are frequently anæmic, and poorly nourished, and that after the tonsils are removed these children often become strong and healthy. The answer is, either that the tonsils are in a pathological condition and consequently not performing their function, or that on account of their over-size they mechanically interfere with respiration to such an extent that their function is practically abrogated.

It would seem at first thought more difficult to explain the perfectly healthy condition of these children who are said to have no tonsils. Upon careful examination, however, lymphoid tissue, either in the fauces, the vault of the pharynx, or base of the tongue, will be found to be present. It is impossible at the present time to agree upon any standard as to the proper amount of adenoid tissue, and quite as difficult to state at what point tonsillar tissue becomes pathologically hypertrophied.

There remains, it is thought, another function of the tonsils, and this, if it does exist, is of far more importance to our paper than the ones mentioned. A warfare is going on at present in bacteriological study. The question in dispute is, in what way is the power of pathogenic

germs rendered harmless in the human body? It is enough for our purpose to state that the larger number of investigators believe that micro organisms are killed or rendered harmless by the *chemical action of the blood serum*, while the minority, at the head of which is Metschnikoff,[1] hold that the real enemies of disease-bearing bacteria and bacilli are the leucocytes or phagocytes; and I draw the inference from their writings that the leucocytes of the tonsils, like those of the alimentary canal, are capable of attacking, receiving, and digesting pathogenic germs.

Now the point we desire to make is, that the tonsillar tissue is in a most convenient location, and it contains the leucocytes to destroy micro organisms if this function—the phagocytic theory—is admitted; or if the blood serum must be reached before germs are rendered powerless to do harm, the germs are, through the tonsillar tissue, carried into the general circulation, so that in either case the function of germ-destroyers may be properly attributed to the tonsils.

It is not within the scope of this paper to discuss fully the details of all the different functions which have been accredited to the tonsils, but in searching for the etiological factors which produce tonsillar inflammation, it has seemed to us most pertinent to state our belief that the tonsils are not only strong auxiliaries to the blood-elaborating system of the body, but that they are also probably capable of destroying pathogenic germs. If this be true, the conclusion is immediately forced upon us that when the function of the tonsils has been destroyed for any reason—as, for instance, by frequent congestions and consequent interstitial thickening, by overgrowth, by disease of the lacunæ, or by an occlusion of the tonsils by the over-reaching of the pillars of the fauces—that when, for these and other reasons, the function of the tonsils is abolished, they no longer destroy pathogenic germs, but their follicles furnish convenient recesses into which micro-organisms may enter, and through which they may easily reach the general circulation.

Radcliffe[2] states that "the materials in a number of septic diseases enter through the crypts of the tonsils and have their manifestations there," and he adds that "the function of the tonsils in absorbing any excess of secretion renders them liable to absorption of septic material."

Jeanselme,[3] in his article on the relation of the tonsil to the production of infection and the entrance of infection into the system, says that unbroken healthy tissue is the best barrier to septic absorption, while the tonsils, exposed to infection both through the alimentary and respiratory tracts, are very liable to absorb septic matter, especially if they be enlarged, if the crypts be open and the epithelium denuded. He states that people with large tonsils are especially susceptible to disease.

John Trumbull[4] cites a case of infective phlebitis resulting from an attack of follicular tonsillitis, and he says "that what begins as a follicular tonsillitis occasionally results in suppuration in or about the gland itself, and in quinsy we have the introduction of septic bacteria into the deeper or surrounding portions of the tonsils, and the absorption may then be along the lymphatics."

A. Fraenkel[5] calls attention to the possibility of infection via tonsils. Haig Brown[6] says that "tonsillitis is not a mere catarrh, but of bacillary origin," and he adds that both rheumatism and tonsillitis appear to be excited by damp weather, but he believes that septic influences are the cause of both.

Lennox Browne[1] recognizes a septic variety of tonsillitis, and thinks the diagnostic point of this variety is that it attacks both sides of the pharynx.

I believe that all severe grades of tonsillar inflammation are septic, due to specific micro-organisms, and I would call sepsis the chief exciting cause of tonsillar inflammation, while the great predisposing etiological factor, and it is, I believe, of more significance than the rheumatic diathesis or the nervous temperament, is the presence of pathological tonsils—tonsils which do not destroy, but which invite pathogenic germs. This, therefore, is our etiology—*sepsis or specific germ the exciting*, and the presence of pathological tonsils the predisposing cause of tonsillar inflammation.

Now to consider more especially the etiology of that special form of tonsillar disturbance called "suppurative tonsillitis." A great deal of confusion has been occasioned by a needless elaboration of acute tonsillitis into a classification of many varieties. We find a division into acute, subacute, and chronic, and we find mentioned such names as simple, catarrhal, superficial, lacunal, follicular, interstitial, parenchymatous, phlegmonous, quinsy, suppurative and non-suppurative tonsillitis, tonsillar abscess, and retro- and peri-tonsillar abscess.

From a clinical point of view, and for teaching purposes, a much simpler classification is adequate, and I would suggest the following:

1. Acute follicular or lacunal tonsillitis, which may become a parenchymatous tonsillitis, and which may, very rarely, be followed by peritonsillar abscess.

2. Acute parenchymatous tonsillitis of all grades of severity, which may or may not be followed by peritonsillar abscess. A chronic parenchymatous tonsillitis is occasionally seen and is caused by the presence of leptothrix elements in the lacunæ of the tonsils.

3. Peritonsillar abscess.

These three divisions really cover the entire ground. The terms, simple, catarrhal, and superficial, are superfluous. They are only used to indicate a mild degree of tonsillar inflammation.

I like Haig Brown's[2] classification into follicular and interstitial tonsillitis, were it not doubtful whether an inflammation of the tonsils is ever confined strictly to the interspaces between the lacunæ of the glands. In all cases the entire structure is probably more or less involved.

The name parenchymatous should be used as indicating the involvement of the entire tonsil. The term acute tonsillitis is not sufficient, because it does not indicate the variety.

I take exception to the terms suppurative and non suppurative tonsillitis, because clinical experience has taught us that when suppuration occurs in this neighborhood, pus is rarely to be found in the tonsil, but may almost always be discovered in the connective tissue, either in front or behind the tonsil, so that the term peritonsillar abscess would seem to be more correct. Retrotonsillar abscess may be discarded as clinically unnecessary.

It would be a waste of time to advocate the use of the name peritonsillar abscess as a substitute for that of suppurative tonsillitis if it were not that the latter name is a misleading one to the physician, who is called upon to locate and evacuate the pus during the course of this disease. We have all made ineffectual stabs into the tonsils too many times in search of pus not to appreciate how gratifying it is to the patient, and how satisfactory to the physician, to know exactly where pus can be reached by a knife at the first attempt. But I wish to speak more fully of this later.

Follicular or lacunal tonsillitis, which is, I believe, a specific disease, due as much to a specific germ as is

diphtheria, is not followed in the majority of instances by an involvement of the whole gland (parenchymatous tonsillitis), and rarely does it terminate in peritonsillar abscess. Professor Koch or his disciples will probably discover the bacillus of follicular tonsillitis, if it is worth while to inoculate against a disease which can so easily be prevented by destroying the tonsil.

As we have said suppuration in the neighborhood of the tonsil occasionally follows an attack of follicular tonsillitis, but in a very much larger percentage of cases it follows parenchymatous tonsillitis. But the question which is of the most importance to us is why an attack of parenchymatous tonsillitis is repeatedly followed by peritonsillar abscess in some people and never in others. We can get over the matter easily by attributing it to heredity, to rheumatic diathesis, or to nervous temperament, but there is little satisfaction in such explanation.

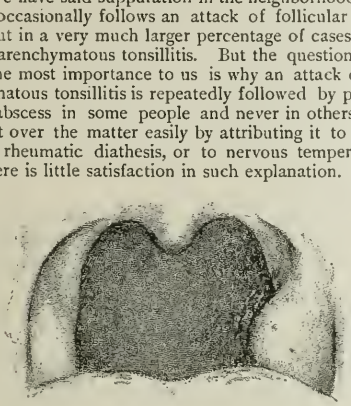

Fig. 1.

I have studied my cases of peritonsillar abscess carefully of late, and I have found in almost every instance that there existed an abnormal relation between the tonsil and the pillars of the pharynx. I have noticed two conditions, one in which the tonsil when in a quiescent state was small, not extending beyond the pillars of the pharynx, but the anterior pillar was not only adherent to it, but intimately grown into the tonsil at a point opposite the upper portion of the tonsil (Fig 1). In the second variety the tonsil was considerably enlarged and was covered by the anterior pillar, the pillar overlapping it to the extent of one-fourth of an inch and adherent to the tonsil at a number of points (Fig 2). I have noticed, too, that the posterior pillars, in cases of repeated peritonsillar abscess, were thickened and were covered by

Fig. 2.

the tonsil, so that it was necessary to draw the tonsil forward to see the whole width of the posterior pillar. I believe that this relation between the pillars of the pharynx and the tonsil plays a more important rôle in the causation of suppuration than does either heredity or any abnormal condition of the blood. It is a very significant fact that this relation exists so constantly in these cases. I am so strongly convinced that this union of palatine fold and tonsil determines in many instances the course which a parenchymatous tonsillitis will follow, that when I examine a tonsil for the first time during an attack of acute inflammation, and find it quite free from adhesions. I feel confident that suppuration will not ensue. More than this, I have in five cases who suffered twice a year from peritonsillar suppuration separated the adhesions between tonsil and pharyngeal pillars, and in three instances there has been no suppuration for more than a year, and in two none for a little less than a year, although all of these patients have during that time suffered from attacks of acute tonsillitis of a mild grade. In none of these cases was the tonsil itself treated.

I have only suppositions to offer in explanation of this relation between tonsil, pharyngeal pillars, and consequent suppuration.

May it not be that in all cases of parenchymatous tonsillitis, whether mild or severe, pyogenic germs are present in and about the glands, but that when a portion of the tonsil—that is, a number of the lacunæ—is covered by and occluded by the pillar of the pharnyx, which either overlaps or has grown into the tonsil, the inflammatory condition is pent up, or in other words, the pus producing germs are not allowed access toward the pharnyx, and so work their way into the tissue about the tonsil, the direction offering the least resistance, and there pus is formed — the peritonsillar abscess? On the other hand, when the tonsil is free from all over-covering of tissue, and the lacunæ are pervious, the parenchymatous inflammation is spent in a few days without any suppuration. Frequent suppuration is to my mind only explained by the condition of the tonsils themselves, and it cannot, I believe, be satisfactorily explained by any diathesis. If it were a matter simply of absorption through large tonsils with widely-open crypts, why do not children suffer from peritonsillar abscess?

Lennox Browne[1] says: "Peritonsillitis often occurs as a result of a low state of the health, which may be the exciting cause." In his experience this variety is generally associated with septic conditions of drinking-water, etc. A low condition of the system and bad hygienic surroundings does not explain the presence of suppuration in cases of peritonsillar abscess in this country, because it does not tally with clinical facts. People in the best of health, and living under the most favorable conditions, suffer from peritonsillar abscess as frequently as any other class.

Writers have always declared, and we all agree, that people who habitually have attacks of peritonsillar abscess have a predisposition to this disease, and without that predisposition they cannot have it. The only matter to decide is what this predisposition is. I believe that peritonsillar abscess rarely occurs, no matter what the exciting cause or the surrounding conditions, except where the lacunæ have been very much encroached upon by a hyperplasia of the stroma of the gland due to frequent congestions, or where the lacunæ are occluded by the pharyngeal pillars.

Richardson Park[2] says: "Quinsy is not produced in insusceptible people by cold or exposure." And he asks: "How do observers who say quinsy is caused by exposure to cold explain that in one cold always produces pharyngitis, in another quinsy?"

The exposure to pyogenic germs must be common to all, but it is only the tonsil in the pathological condition described that suffers from the attack. Although pus almost always collects in the peritonsillar connective tissue we believe the infection is received through the tonsil, and it may even be possible that the first pus-forming centre is in the tonsil, and that it quickly works its way into the connective tissue in front or behind the tonsil, where it is found by the surgeon. That peritonsillar abscess is not a disease of the pharyngeal pillars or of the peritonsillar connective tissue alone would seem to be proven by the fact that it almost never occurs after the tonsil has been thoroughly destroyed by the galvano-cautery.

One significant clinical point which should have been mentioned is that in former years, when little attention was paid to the use of antiseptics in nasal surgery, an operation on the nasal septum was frequently followed by an attack of follicular tonsillitis, and I remember two

[1] Diseases of the Throat, p. 224.
[2] Park, J. Richardson: New York Medical Journal, July 20, 1890.

instances where such operations seemed to be the direct cause of peritonsillar abscess. The infection was derived from the unclean wounds of the nose.

We cannot well pass on to the treatment of peritonsillar abscess without referring to the predisposing causes of this disorder which many writers lay great stress upon. There is no dispute as regards sex; men suffer from peritonsillar suppuration twice as often as do women. Exposure, smoking, drinking alcoholic stimulants explain this. While some writers claim that heredity is a strong predisposing factor in parenchymatous tonsillitis, I do not know that they have traced such connection specially in their cases of suppuration about the tonsils. I have never been able to satisfy myself that heredity played any important part. The history we get from the present generation in regard to the condition of the throats of their ancestors is not very valuable. G. F. Boucsein found that six cases out of forty-three gave history of family disposition to tonsillitis, and Haig Brown's statistics give ten out of one hundred and nineteen cases as having hereditary tendencies to tonsillitis.

Hundreds of pages have been written during the last few years concerning the relation between rheumatism and tonsillitis, and some writers seem anxious to prove that every sufferer from acute tonsillitis is rheumatic. Such enthusiasts tell us that a description of one disease would perfectly answer for the other, and the newest remedies for tonsillitis are administered because they have been proved efficacious in rheumatism. We quote from a few writers:

Lennox Browne [1] says: "I have long been of the opinion that the darthous or arthritic diathesis invariably exists in those patients subject to recurrent attacks of tonsillitis."

Radcliffe [2] says: "There can be no doubt of this relationship, because remedies that cure one will cure the other," and suggests that there may be a rheumatic germ that enters the tonsil.

Jonathan Wright [3] says: "In severe cases of tonsillitis there is an undoubted rheumatic taint."

Barclay Brown [4] says: "The relation between rheumatism and tonsillitis is so intimate that the condition of the heart should be ascertained in people who suffer from tonsillitis."

Charles Warden "has never seen a case of acute or chronic rheumatism without congestion of the tonsils."

Boucsein finds that fourteen per cent. of people who suffer from tonsillitis have rheumatism, and Haig Browne says that seventy-six out of one hundred and nineteen patients suffering from acute tonsillitis had rheumatic tendencies, and he thinks heart disease commonly caused by tonsillitis. His explanation is that a specific germ finds its way into the tonsil, inflames it, and then attacks the fibrous and serous structure. The statistics showing the relation between rheumatism and tonsillitis range from fourteen to eighty per cent. However close the relationship between rheumatism and ordinary attacks of tonsillitis may be—and I have not been able to get an authentic history of such relationship in more than six per cent. of my cases—I have found rheumatic history in only three out of twenty four cases of peritonsillar abscess.

As I have said, believers in this relationship advocate in the treatment of tonsillitis remedies which are of the greatest benefit in rheumatism, such as the salicylate of soda and lithia. Salol, grs. x. every two hours, is the last addition, and although it seems to control the pains of tonsillitis in a remarkable manner, Gougenheim, who has used the drug considerably, says that it has never been known to abort a case of suppuration about the tonsils. Benzoate of sodium is another drug used on the supposition that tonsillitis and rheumatism are very closely akin. Five-drop doses of Norwood's tincture of veratrum viride, combined with small doses of morphia, has recently been extolled as a remedy of great efficiency in tonsillitis.

Before speaking of the surgical treatment of peritonsillar abscess, I wish barely to allude to an article written by J. Richardson Parke: [1] "An Inquiry into the Relationship of Amygdalitis to the Cerebro-spinal Centres."

After describing carefully the nervous supply to the tonsils, and showing the intimate relation between the different cranial nerves going to this region with those of the sympathetic system, he cites cases; one in which a blow on the back with a belt caused an attack of acute tonsillitis, and another where quinsy followed the nervous shock caused by reading an account of a fire. He believes that strong mental impressions are able, in a reflex manner, to close the orifices of the lacunæ of the tonsils, and inflammation results.

The surgical treatment of peritonsillar abscess remains to be spoken of. Clinical experience has taught us that we possess no drug which can be depended upon to shorten an attack of parenchymatous tonsillitis; careful observation has repeatedly shown that all attacks of acute tonsillitis not followed by suppuration tend to improve after the third day without medication, and we know of no drug which will shorten the period of exacerbation, and certainly none that will abort an impending attack of peritonsillar abscess, so that when suppuration in this region has commenced it is clearly the duty of the physician to hasten suppuration and to evacuate the pus as early as possible. Every moment of pain that can be saved the patient during this distressing disease will be appreciated. I do not propose to speak of the medical treatment of these cases. I will only add that I have found hot applications of more benefit than cold ones; they relieve pain to a greater degree, and bring the abscess to a termination more rapidly.

The most important point in the treatment of peritonsillar abscess is to locate the exact point at which pus is forming as early as possible. And I believe we may say that it will be found in one of two places, either between the anterior pillar and the tonsil or in the posterior pillar. The pus is not generally located below the plane of the dorsum of the tongue. The reason pus is oftentimes located so late in the disease is because the pharynx cannot be properly examined without good illumination, the use of cocaine, and plenty of time. And these three things are not always at the command of every physician. It is well, as a routine practice, when we first see these cases, unless we have had charge of them from the beginning, to apply cocaine, a ten per cent. solution, to the tonsil itself, so that by its contraction the pillars of the pharynx will be freely exposed. The posterior pillar is usually completely hidden until this is done. Some of the most satisfactory cases of peritonsillar abscess I have seen have been those in which, as soon as the tonsil was shrunken by cocaine, a bag of pus was exposed in the posterior pillar.

A physician of this city who suffers from periodical attacks of peritonsillar abscess sent for me a few months ago. I found him in great distress. He had had his tonsil scarified every day for three days without relief. I found a collection of pus in the posterior pillar, hidden beneath and behind the tonsil. The pus is to be found more often, however, in the connective tissue, just in front of and a little external to the tonsil, and several days are required to bring the pus out to a point where it can be reached with a knife. I sometimes resort to an expedient which has proven useful in these cases. I puncture through the anterior pillar only to the depth of one-fourth of an inch with a narrow-bladed tenotomy knife—sometimes I have made this puncture with a galvano-cautery point. I then insert a large-sized probe and pass it down into the connective tissue lying at the anterior external

angle of the tonsil, and I make it a point to pretty thoroughly break up the connective tissue along the course of my probe. I have found pus in a number of cases at an early stage in this way, but I do it principally because it relieves tension and favors the passage of pus in this direction. It is of course perfectly safe to pass deeply into the tissues with a probe where the use of a knife would be unsafe. The opening thus made is kept open by the daily passage of the probe. I have not found that this procedure increased the irritation, but, on the contrary, decreased the inflammatory swelling. We must never omit to search for pus down in the lower pharynx, in front or behind the tonsil. Here unrecognized pus sometimes produces dangerous swelling and dyspnœa. Pus will almost never be found in the tonsil itself until at a late period of the attack, and then I think it has worked through into the tonsil from the tissue about the gland. Scarification of the tonsil almost always does harm and should not be persisted in. The use of strong solutions of cocaine, twenty per cent., applied frequently to the tonsils, as advocated by some writers, may prove a dangerous therapeutic measure. I have usually found that the swelling is greater after the effect of the cocaine has worn away than before its application, and I cannot refrain from adding that I believe morphia to be a dangerous drug in any considerable dose. Patients need all their faculties to enable them to clear their pharynges of mucus, saliva, and pus. Poultices, steam inhalations, hot gargles will all hasten the end of the attack.

Happily it is in our power to relieve our patients from suffering from future attacks of tonsillar inflammation. When a tonsil shows itself competent, at short intervals, to absorb septic material, to become inflamed, and to induce suppuration in its neighborhood, it is clearly in a pathological condition, and it should be destroyed. It is agreed that excision is the best measure to rid children of enlarged tonsils which interfere with respiration and deglutition, but in the case of adults, and young adults who suffer constantly from follicular and parenchymatous tonsillitis, some of whom are disposed to suppuration about the tonsils, here the tonsils are, as a rule, not large, many of them are too small to excise, and many of them are so congested that the use of the galvano-cautery point or écraseur is deemed safer than the tonsillotome. In these cases by destroying a portion of the tonsils we can nearly always promise our patients immunity from further attacks of tonsillitis. Why should we spend so much time over the discovery of new drugs when we can so easily prevent tonsillar inflammation? It is remarkable how little of a tonsil needs to be destroyed to completely check its disposition to inflammatory attacks—one or two linear incisions through the length of the tonsil with the galvano-cautery electrode, and these need not be deep, has in my experience been sufficient to prevent further attacks of tonsillitis. Great care should be taken to separate adhesions between the tonsils and the pillars of the pharynx.

The many objections to the removal of large tonsils in children, which have been proven to be groundless, are not urged against the partial destruction of smaller tonsils in adults. The only uncomfortable result I have ever noticed following the burning of a tonsil was a dryness of the pharynx, but this was only a temporary condition, lasting but a few weeks. This would seem to prove that although the tonsil may not secrete lubricating fluid, there is glandular tissue intimately connected with it, which does.

I need not say that the galvano-cautery should be applied very carefully, that no harm should be done to the pillars of the pharynx, to the uvula, or to the tongue. Where there is an overlapping of the pharyngeal pillars they should be separated from the tonsil with the handle of a bistoury before the tonsil is burned, and it is well to apply to the raw surfaces a solution of mercuric bichloride—1 to 1,000—by means of a cotton pledget, though the cautery is a very efficient sterilizer. When the anterior pillar presents a second redundant fold, it must be burned down to the normal line of the anterior pillar. If the tonsil requires more than one burning (and it is possible to destroy a large tonsil at one sitting), the redundancy of the anterior pillar should not be touched with the cautery until the last burning, so that the patient will suffer as little pain as possible. Very little inflammatory reaction and pain follow injury to tonsillar tissue, but the pharyngeal pillars resent any traumatism. If the tonsils are quite large, as they occasionally are in adults, burning the entire mass from the external surface is too slow a process, and the use of the hot loop, the galvano cautery écraseur, as recommended by Dr. C. H. Knight, may be used with advantage, but this procedure requires skilful manipulation. I have resorted to two expedients in the treatment of large tonsils, where I did not care to use the tonsillotome after the usual method. I have first punctured the tonsil to the depth of the pillars of the pharynx, perhaps ten times, with the galvano-cautery, in order to destroy the blood vessels, and have then removed the undermined tonsils with scissors or with the tonsillotome. The electrode is introduced into the anterior, not the inner, surface of the tonsil.

I have also, in some cases of enlarged congested tonsils in adults, used a dull tonsillotome, and have pushed the blade through the mass slowly, consuming several minutes in the operation. This would be something on the principle of the use of the cold wire. I find that adult patients can easily tolerate the tonsillotome in the mouth for some time, if the head is inclined forward so that the saliva can flow out of the mouth. The pain is not great. Cocaine should not be applied to the tonsils where cutting is to be done, because it compresses the tonsils into a small hard mass, and because it drives all the blood out of the tonsils, and hemorrhage may occur when the effect of the cocaine has worn away and the patient has left the physician's office.

In conclusion, I would like to state my belief in the following propositions :

First. That the tonsils, like other lymphoid tissue, are blood-elaborating glands.

Second. That when they are in normal condition they probably perform a second function by reason of the large number of leucocytes contained in them, and this function, if not aggressive, at least possesses the power to prevent the entrance of pathogenic germs through the crypts of the tonsil.

Third. That when the tonsils have ceased to perform their function, by reason of such pathological conditions as interstitial thickening and occlusion of the lacunæ of the glands, they probably present open mouthed viaducts through which pathogenic germs may pass to the lymphatic circulation.

Fourth. That all kinds of tonsillar inflammation are due to septic causes, or in other words to specific germs, and that those causing follicular disease, parenchymatous disease, and peritonsillar abscess, are different from one another.

Fifth. It is believed, therefore, that septic influences are the exciting cause of tonsillar inflammation, and that the presence of pathological tonsils—tonsils unable to perform their physiological function—is the chief predisposing cause.

Sixth. That a classification of tonsillar inflammation into three varieties is sufficient, viz, follicular, parenchymatous, and peritonsillar abscess.

Seventh. That suppurative tonsillitis is not a correct name, because the suppuration occurs in the connective tissue about the tonsils and very rarely in the tonsils themselves.

Eighth. That in people who possess the disposition to suppuration about the tonsils we find the tonsils either adherent to, or covered by, the pharyngeal pillars, and that this condition plays a more important rôle in the predisposition to suppuration about the tonsil than does the rheumatic or other diathesis.

Ninth. That when a tonsil shows itself competent at

short intervals to become inflamed or to give rise to peritonsillar suppuration, it is in a pathological condition and should be destroyed by the galvano-cautery or by other measures.

THE NON-OPERATIVE TREATMENT OF DELAYED UNION IN FRACTURES OF THE LEG.[1]

By JOHN RIDLON, M.D.,

Consulting Orthopedic Surgeon to the Transfiguration Clinic. Assistant Surgeon to the Vanderbilt Clinic, New York.

I desire to present to you two patients who have suffered from delayed union of fractured bones of the leg, to ask your inspection of a modification of the caliper splint for the treatment of conditions of this kind, and to call to your attention certain additional means for the non-operative treatment of delayed union in fractures in general, which, though by no means new, are not generally known, and, in so far as I know, not used in this country.

The histories of my two cases are as follows:

Case I.—Thomas C. B——, aged thirty, unmarried, no constitutional disease. On March 22, 1888, while leading a dog across a street, jumped to escape a passing team, was pulled around by the dog and landed obliquely and with a twisting motion on right foot; felt pain and fell to the ground, but sprang up to escape being run over, and made his way to the curb. Was removed in a cab to his home, where it was found that he had sustained a compound fracture of the right tibia somewhat below its middle part. A surgeon of skill and great experience was called at once, the wounds were dressed and the fracture put up in light board splints and a fracture-box. The next day a surgeon of world wide reputation took charge of the case, and the leg was enveloped in a plaster-of-Paris-dressing. This dressing was removed at the end of two or three weeks, when the wound was found to have healed. The plaster splint was renewed from time to time; and on September 17th, he entered Roosevelt Hospital and was operated upon by Dr. Frank Hartley, to whom I am indebted for access to the hospital records, and who subsequently transferred the case to my care. On his admission to the hospital it was recorded that the "motion at fracture is slight." When the seat of fracture had been exposed at the operation, "an oblique fracture of the tibia is found, passing from below upward, with plane looking forward and upward. The interspace between the fractured surfaces of the upper and lower fragments is filled with a thin wedge-shaped piece of fibrous tissue, which was perhaps externally muscular. The divergence, greatest below, did not exceed one-half inch. At the inner edge of the fractured surfaces is a thin line of bony union." The opposing oblique bony surfaces were chiselled, drilled, and wired, and the leg put up in a plaster-of-Paris dressing. He remained in bed thirty-one days, but the union was not solid when he returned home four days later, on October 22d. The plaster splint was continued, and the patient went about the house with crutches.

On December 27th I saw the case in consultation with Dr. Hartley, who then transferred him to my care. On January 10, 1889, the plaster was removed and a supporting steel splint applied. At this time there was distinct antero posterior motion at the point of fracture, and though there was evidently soft union between the fragments, there was no appreciable callus to be felt about the fracture. There was some tenderness on pressure and on motion at the point of fracture. Only moderate constriction was made, as the dependent position after the removal of the plaster sufficed to give abundant œdema. The patient began to go about out of doors at once and visited my office two days later. When I next saw him, at the end of nine weeks, union was perfectly solid and abundant callus could be felt. He informed me that he had continued the use of the crutches for some time; and that he had removed the upper supporting part of the splint at the end of the third week as it was somewhat uncomfortable. The lower portion of the splint, which acted only as a lateral support, he continued to wear for about five months.

The patient recently volunteered the statement that he believes that the delay in union was due to constantly moving the bones at the point of fracture within the plaster splint during the first weeks of the treatment.

Case II.—William D——, aged twenty-two, unmarried, no constitutional disease, presented for treatment at the Vanderbilt Clinic on September 8, 1890, and on the 22d of the same month was transferred to my care. In reply to inquiries as to his early history Dr. William T. Bull writes, under date of November 26th: "The history of William D—— is now in the hands of the binders, but I give you the following from my own remembrance, and that of my house surgeon at the New York Hospital. William D——, aged twenty-two, admitted to New York Hospital May 26, 1890, history of having been run over by a wagon. Examination reveals a compound comminuted fracture of the right leg at the middle and lower thirds. A large lacerated wound anteriorly, through which the bones project. Great displacement. Much contusion and laceration of soft parts. Under ether, loose fragments removed, bones replaced, hemorrhage stopped, thorough drainage at all dependent points. Plaster splint over antiseptic dressing. Rise of temperature necessitated change of dressing at end of forty-eight hours. Volkmann's splint applied for three weeks, then plaster splint with fenestrum and frequent dressings. Wounds gradually closed. Delayed union. Necrosis. Discharged by superintendent of hospital for insubordination August 5, 1890. Had walked on crutches, partly on leg, for three or four weeks before discharge. Some deformity and delayed union on discharge. I am not certain whether all sinuses were closed. Plaster splint on leg on discharge."

When the patient came under my care on September 22d all wounds were healed; no callus could be felt about the point of fracture; there was tenderness on firm pressure, and on motion at the point of fracture; soft union was believed to exist because the fragments could not be displaced, although there was very considerable motion possible in all directions. The plaster splint was discontinued, and the splint shown in the illustrations applied. The splint is nothing more than the caliper splint of Thomas, of Liverpool, so modified as to permit of no motion at the ankle, and with the laced leather sleeve added. The splint is made from three-eighth inch iron wire; the ring in which the patient sits is irregularly ovoid in shape, and follows approximately the outline of the thigh; it is joined by welding to the upright bars at an angle from within outward, and from behind forward, so that the lowest point of the ring comes underneath the tuberosity of the ischium; the angle of the ring with the inner bar from within outward is about one hundred and thirty-five degrees, and from before backward about one hundred and twenty five degrees; the lower ends of the side bars plug into vertical tubes that are joined by a shank which is riveted to the sole of the shoe; a band buckled across the front just above the patella prevents forward bending of the knee; a band below the knee at the garter line surrounds the leg and the outer bar, and furnishes the means by which the circulation is dammed, and is under the control of the patient. The laced leather sleeve may or may not be used. It is a matter of some comfort to the patient, as it prevents the leg from chafing against the side bars, and it possibly acts in some measure to immobilize; but if it is used care should be exercised that it is not sufficiently tight to check the desired œdema. Of course it should be unnecessary to say that the splint

[1] Read before the Orthopedic Section of the New York Academy of Medicine, December 16, 1890.

remains on continuously, and that the shoe is a part of the splint. In this patient, solidification has slowly but steadily increased, and abundant callus has been thrown out.

The patient has been seen only at intervals of from one to two weeks; and motion was not carefully tested

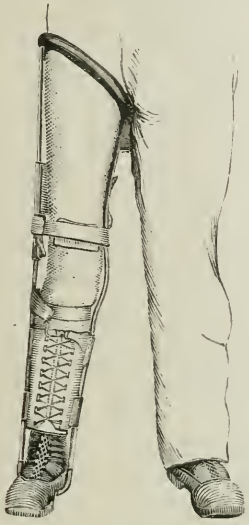

Fig. 1.

till the end of nine weeks, when no motion could be detected and the patient walked across the room without the splint or any support. He felt, however, some sense of weakness and tenderness in the part. After the application of the splint he continued the use of one crutch for a short time only, and he was soon able to walk three or four miles without discomfort, and after eight weeks resumed his laborious work of unloading vessels.

In speaking of delayed union, I do not use the term as synonymous with *non-union*, or *pseudarthrosis*. Neither do I use it in precisely the same limited sense that it is generally used by writers who would place a time limit, more or less movable to be sure, upon the term, and make subjective pain and tenderness play an important part in the diagnosis. A given case cannot rightly be denominated delayed union this week, and non union next; nor delayed union while pain and tenderness exist to-day, and non-union when they are no longer felt on the morrow. The normal union of a fractured bone occupies a pretty definite period, and if union fails to be perfect at the end of that time either delayed union or non-union may be said to exist; but if it be delayed union in the beginning, delayed union it will remain until it has become solid by non-operative treatment; while if it be non-union in the beginning, non-union it will remain until cured by operation. Non-operative treatment has no place in the treatment of cases of true non-union, and we will not further consider that branch of the subject, however interesting it would be to discuss the query as to why union is more readily obtained in cut off than in broken off bone ends. In the same way we believe that operative measures have no place in the treatment of cases of delayed union. For time is not a subject for consideration when weighed in the balance with the risk to life of even an aseptic operation; and no cutting operation should be thought of until every other known means and an abundance of time have been expended.

As orthopedic surgeons more than our rightful share of these unpromising cases will come under our observation. During the past two years I have met with delayed union in two fractures of the leg, two of the shaft of the femur, one of the neck of the femur, and one of the humerus. The two cases of fracture of the leg I have presented to you. It therefore behooves us to take counsel one with another as to what causes these delays in the perfect union of fractured bones, and as to how we can best contend against the evil results that have been wont to follow.

In the works on general surgery, and in those works specially devoted to the consideration of fractures, various causes are laid down for delayed and ununited fractures; but two, however, need detain us, and these only because the present fashion of treating fractures by plaster-of-Paris bandages conduces to the one or the other, namely, constriction of the seat of fracture, or to deficient immobilization. Bandages of plaster-of-Paris are so readily obtained, so easily applied, so wholly safe from interference on the part of the patient, and so comfortable withal that it is not surprising that they have come into general use in the treatment of fractures, especially outside of hospital practice. It appears to the writer, however, that no dressing has ever been devised for the treatment of fractures which so illy accomplishes the end in view, namely, immobilization without undue compression of the part. I would not deny that it is possible to use plaster of-Paris as a dressing for fractures without harm, but I do hold that for its proper use is required a greater skill and experience and a higher grade of intelligence on the part of the surgeon than for any of the other dressings. To swathe a broken limb in plaster-of-Paris and to then trust in God for the result may be evidence of a sublime faith, but it is also frequently evidence of very cowardly surgery.

Plaster-of-Paris when used for fractured bones is applied either before or after swelling has taken place. If applied before, it constricts the seat of fracture, prevents the normal amount of swelling, and literally strangles the life out of the young callus; in a certain number of cases delayed union results. If applied after the swelling has taken place, it becomes loose as soon as the swelling of

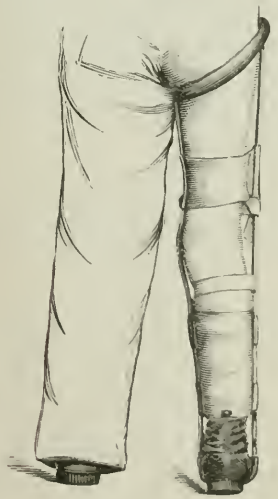

Fig. 2.

the soft parts subsides, motion of the limb in the splint and of the fragments of the fractured bone one upon the other is possible, and again in a certain number of cases delayed union is found when the splint is removed.

The treatment of delayed union in fractured bones I take from that most original and ingenious of surgical thinkers, Hugh Owen Thomas, of Liverpool. It consists in "hammering, damming, depending, and fixing" the

bones involved in the fracture. Thomas first hammered the seat of fracture in March, 1874, with a copper mallet faced with rubber; later he protected the skin with basil leather and used an ordinary carpenter's hammer; he now uses an egg-shaped wooden mallet. The hammering may be done with or without an anæsthetic, but should not be repeated at too frequent intervals. Probably once in two weeks is sufficiently frequent, though more observations on this point are needed. He first used damming in 1876, by means of a tourniquet applied intermittently for a period of ten minutes once each day. Gradually the duration of each *séance* was extended and their frequency increased until, in 1881, we find him employing continuous damming. To what point shall the interference with the circulation be carried is a question that will occur to you. I do not think I err in saying that it should be sufficiently complete to cause abundant œdema, but not enough to cause pain or interfere with the nutrition of the limb. In going over the thirty-nine cases reported by Thomas in 1885 we find a gradual diminution in the frequency and severity of the hammerings and an increased reliance upon damming, until now we find him damming all and percussing some.

The advantage of making the limb dependent has long been recognized and need not be dwelt upon here.

To properly immobilize the fracture is probably the most important of all; certainly none, except damming, at all approach it in importance. Delayed union may often be made solid by hammering, damming, and depending without any fixation at all; but if fixation be employed improperly, that is, so as to circumferentially constrict the fractured point, all the percussing and damming in the world will not be of avail. To properly fix a limb the bones must be held by a grasp which does not circumferentially constrict the seat of fracture, and the muscles covering the part must be lulled to rest by continuous fixed traction, and not nagged by an elastic or an intermittent traction; further, the joints which it is the function of these muscles to move must be absolutely locked. When a fracture exists in the bones of the leg, as in the cases reported, the knee and ankle must both be locked. The splint of Dr. H. H. Smith, of Philadelphia, figured in most of our works on fractures, is open to the objection that it immobilizes neither knee nor ankle, and the caliper splint of Thomas is open to half that objection, in that it allows motion at the ankle. This fault I have endeavored to obviate in the splint which I have presented to you.

337 West Fifty-seventh Street.

A CASE OF CHRONIC ABSCESS OF THE ABDOMINAL WALL, SIMULATING MALIGNANT INTRA-PERITONEAL TUMOR.[1]

By H. C. COE, M.D.,

NEW YORK.

On March 8th I saw, with Dr. Walter Mendelson, Mrs. P——, aged sixty, whose health had been poor for several years, being consulted with reference to an abdominal tumor, which had been discovered a month before by Dr. Partridge in the New York Hospital, where she was under his care for acute lobar pneumonia. So far as I could learn, the mass then appeared to be intra-peritoneal. It had increased in size quite rapidly, and had grown outward, so as to form a projection above and to the left of the symphysis pubis, and had become quite painful. On examination I found a neoplasm, which I estimated to be as large as a cocoa-nut, occupying the left hypogastric region and extending over into the left iliac. Its attachment was deep, but it involved the skin, forming a projection in the latter the size of a small lemon. The skin over the nodule was somewhat reddened, but I could detect no fluctuation. Temperature and pulse normal. The patient presented a fairly marked cachexia, and struck me as being a most unfavorable subject for an operation. I regarded the tumor as probably malignant, and inferred that it had originated in the peritoneum and extended outward, as I had observed in other cases. Examination per vaginam showed that it was not connected with the pelvic organs. By my advice she was sent to the Cancer Hospital, where she was kept under careful observation for several days. Soon after entrance she began to have a slight evening rise of temperature (100° to 100.5° F.), and obscure fluctuation could be felt in the superficial nodule. She had little, if any, local pain. The patient's general condition was bad; her heart was weak, and her urine contained albumin and casts. She was anxious to have something done, and, though neither my colleagues nor myself were able to determine positively whether the tumor was of intra-abdominal origin, or was purely mural, it seemed to be justifiable to at least explore and evacuate any pus which might be present. The prognosis in any case was bad.

With the patient under chloroform anæsthesia, and assisted by Dr. Shrady, I made an incision to the outer side of the mass, and found that the superficial nodule was an old, thick-walled pus cavity, which contained about half an ounce of pus. This was freely incised, washed out, and explored; it seemed to be simply subcutaneous, its floor resting upon the main mass of the tumor. While palpating the floor my finger entered a second cavity, having no apparent connection with the first, which contained at least six ounces of pus. As soon as the latter was evacuated the hemorrhage from the walls of the sac became so free that I extended my incision and excised all the superficial mass, in order to expose the cavity. Its floor was formed by the abdominal muscles, and its lateral walls were of cartilaginous consistence. It was the opinion of all who were present that the condition was probably sarcoma originating in the muscle or its sheath. At this stage in the operation the patient collapsed, and was with difficulty kept alive until I had finished. I removed as much of the diseased tissue as possible, dissecting down, outside of the peritoneum, into the iliac fossa, where it was firmly attached, packed the cavity with iodoform gauze (the hemorrhage had ceased), and put the patient in bed. She did not rally, her kidneys absolutely refused to act, and she died thirty six hours later.

The specimen was examined by Dr. George C. Freeborn, the pathologist, who reported as follows: "The growth was received in two parts. The external portion is covered with skin and a thick layer of fat, there being a subsequent layer of soft reddish tissue, averaging 3 mm. in thickness; the internal portion averages 1½ ctm. in thickness, and is composed of two layers; an inner, dense and white in color; and an outer, soft, reddish, and with an irregular nodulated surface. Microscopically the external or cutaneous portion presents a layer of connective tissue infiltrated with pus-cells, and a layer of granulation tissue œdematous and necrotic in spots. The internal portion consists of a wide band of dense connective tissue, along the internal edge of which are a few degenerated striated muscle-fibres; scattered through this layer are several necrotic areas. The reddish sub-layer shows the same structure as in the external portion of the growth. Diagnosis, chronic abscess." The autopsy showed fatty degeneration of the heart, with disease of the mitral valves, old general pleuritic adhesions, and chronic diffuse nephritis. There was also chronic cystitis, the bladder containing a quantity of muco-pus. The abscess was entirely mural, but just where or how it originated was not clear. The interesting points were:

1. Diagnosis. How could one tell what the nature of the tumor was, and if it was not originally intra-peritoneal? It is common to have malignant tumors extend through the abdominal wall and involve the skin. Even though it showed signs of suppuration, it seemed to be malignant. In a recent doubtful case of chronic abscess at the upper edge of the breast, in which I amputated the entire mamma simply on suspicion, the tumor proved to

[1] Read at a meeting of the New York Clinical Society, May 30, 1890.

be a carcinomatous nodule that had undergone suppuration.

2. The two abscesses, apparently distinct. There was no indication of the deeper, and few or no symptoms except those due to the superficial one.

3. Advisability of making an incision below the growth and parallel with Poupart's ligament, instead of an exploratory laparotomy, as was suggested to me.

4. Difficulty of making out the relations of the mass, and the close resemblance to an extra-peritoneal sarcoma, growing from the muscle.

A FARTHER STUDY OF ANODAL DIFFUSION AS A THERAPEUTIC AGENT.[1]

By FREDERICK PETERSON, M.D.,

ATTENDING PHYSICIAN TO THE NEW YORK HOSPITAL FOR NERVOUS DISEASES.

In a paper read before the Section on Theory and Practice of the New York Academy of Medicine in February, 1889, I called attention to the therapeutic value of the cataphoretic power of electricity, to which power I gave the name anodal diffusion.[2] The ability of a galvanic current, in flowing from the positive to the negative pole, to seemingly carry substances with it even through a membrane, or through the skin, has been affirmed by some, but even to this day denied by other authorities.

Dr. B. W. Richardson first drew attention to what he termed voltaic narcotism in two articles in the *Medical Times and Gazette* in 1859. He produced local anæsthesia with solutions of morphia, aconite, and chloroform; but the storm of opposition aroused over Europe made him subsequently abandon what was an actual discovery.

H. Munk killed rabbits by placing a solution of strychnia upon the anode and applying it to the skin of the animals for a few minutes with moderate currents. Quinine and potassium iodide had also many years ago been experimentally introduced by cataphoresis and quickly detected in the urine.[3]

Nothing further was published until 1886, when Wagner[4] printed a short note expressing a belief that anæsthesia might be produced by the use of cocaine on the anode. He made no experiments.

In the same year Adamkiewicz[5] introduced his diffusion electrode and described his experiments and successes with chloroform in the production of anæsthesia and the relief of pain.

The conclusions of Adamkiewicz were attacked by Paschkis and Wagner,[6] who claimed that the contact of the chloroform with the skin was sufficient to produce the anæsthesia, and that the galvanic current had nothing to do with it, for the resistance of chloroform was so great that it could not conduct at all.

Lumbroso and Matteini[7] employed chloroform the same year with ordinary electrodes for the relief of neuralgia.

Dr. Corning,[8] of this city, produced anæsthesia with a five per cent. solution of cocaine on the anode after pricking the skin with needles. This was also in 1886.

Dr. Reynolds,[9] of Chicago, published in 1887 an article upon the use of cocaine in two to twenty per cent. solutions with the anode in his dermatological practice for small cutaneous operations, and for the electrolysis of hair roots. He also used voltaic narcotism in one case of tooth-extraction as had been done by Richardson just thirty years before. Owing to the publication of Dr. Reynolds's paper in the journal mentioned, it escaped my notice altogether, and was not included in the list of authorities given in my first paper. I am under obligation to Dr. R. H. M. Dawbarn for kindly calling my attention to it. Although Wagner and Corning had separately written about cocaine cataphoresis before Reynolds, they had not given it as great practical application as the latter.

When I took up the subject of anodal diffusion in the winter of 1888 and 1889, the bulk of information at my command was limited and uncertain. There was so much controversy on every point, so much diversity of opinion, that even the existence of the cataphoretic power of electricity seemed to be as yet not scientifically proven. I therefore made some hundred experiments upon myself and patients, the most important of which were detailed in my first paper already referred to.

The results of previous experiments may be summed up as follows:

The current alone does not produce anæsthesia at either pole, although the anode has a transitory soothing effect over painful foci.

A watery solution of cocaine applied to the skin is not absorbed, does not produce anæsthesia, except perhaps after an indefinitely long period. The same is true of chloroform, and of an alcoholic solution of aconitia.

A watery solution of cocaine is diffused through the skin and subcutaneous tissues by the anode, but not by the cathode. This is true of chloroform, aconitia, strychnia, potassium iodide, corrosive sublimate, tincture of iodine, and other medicaments.

The anæsthesia produced by a ten to twenty per cent. solution of cocaine on the anode is sufficient for small operations, and affords distinct relief for from four to eleven hours in cases of severe neuralgias in superficial nerves, and without constitutional effects.

The Adamkiewicz electrode is absolutely worthless, since it is so stupidly constructed that the current does not pass through the fluid contained within it, but through its circular metallic rim.

Chloroform, recommended by Adamkiewicz, and by Lumbroso and Matteini, should only be used for cataphoretic purposes when, in addition to producing a local anæsthesia, it is desired to counter-irritate, for it causes a disagreeable dermatitis of a week's duration, as I have had reason to learn by experiment upon myself. It does induce a deep analgesia beneath the anode, but it also vesicates.

Up to February, 1889, I had employed anodal diffusion of solutions of cocaine and aconitia, separately or mingled, in two severe cases of chronic supraorbital neuralgia selected for me as crucial tests by Dr. Seguin; in one case of double trigeminal neuralgia; in one case of inferior maxillary neuralgia; in one case of locomotor ataxia for the relief of dorsal neuralgic pains. The success of the measure in all of these cases was undisputed. It gave hours of relief from excruciating pain and without constitutional effects of any kind. Nothing was claimed for it as a curative procedure, but it certainly proved to be a more than efficient substitute in these cases for morphine, which, as we too well know, is so prone to exact for its hours of solace lifetimes of wreck and ruin.

Since the publication of my paper other articles which serve to show the growing recognition of the value of the method have emanated from various sources. Dr. Cagney,[1] of London, reported his experience in the use of cataphoresis before the Harveian Society, November 7, 1889. He employed iodine and a saturated solution of potassium iodide with the anode for labyrinthine deafness, lead palsy, small tumors of the skin and mucous membranes; for syphilitic and other throat affections; for chronic pharyngitis; for nodes and gummata, tubercular ulcers, mucous patches and papular syphilides; for indolent ulcers, lupus, acute and strumous glands. In the discussion upon Dr. Cagney's paper, Mr. Juler stated that he had found the method useful in tobacco amblyopia.

In the same month, Drs. Gärtner and Ehrmann [1] made a communication to the Imperial-Royal Society of Physicians, of Vienna, in reference to the cataphoretic use of corrosive sublimate. Dr. Gärtner's electric bath-tub was employed, from 4 to 6 gms. of mercuric bichloride being dissolved in the water of the bath. A current strength of 100 milliampères was passed through the person experimented upon for fifteen or twenty minutes, and subsequently mercury was found in the urine in as large a quantity as 1.3 milligr. There were traces of the metal in the urine for from four to six days after the bath.

Some time ago Boccolari and Manzieri [2] announced their intention to study the effects of electric cataphoresis in connection with mineral baths, but I have been able to find no published record of the results of their studies in this direction. They have published, however, their use of anodal diffusion of drugs in parasitic affections of hair roots.

Woodbury [3] described in May, 1890, his successful employment of the anode with a solution of iodide of lithium in a case with a syphilitic cutaneous neoplasm.

Shoemaker [4] has also written upon the uses of cataphoresis in certain skin diseases.

Dr. A. Barth [5] describes cocaine cataphoresis as employed by him in a number of operations upon the tympanum and external auditory meatus, finding a ten per cent. solution on cotton connected with the anode very successful.

At the International Congress held at Berlin in August 1890, Dr. Bayles, of Orange, N. J., read a communication from Mr. Edison, the inventor, upon the medical employment of cataphoresis. The transactions of the Congress not yet having been published, I am indebted to my friend, Mr. A. E. Kennelly, Chief Electrician of the Edison Laboratory, for the following brief synopsis of Mr. Edison's experiments:

"The first trials were purely physical. With a current of twenty milliampères, lithium chloride was forced through a septum of animal membrane by electrical endosmose.

"The second series of trials was upon the person of a healthy young laborer, who dipped one hand in a solution of common salt, and the other in a five per cent. solution of lithium chloride in water, for two hours daily for ten days. His urine examined before the test showed no more than mere traces of lithium. His urine collected during that period exhibited distinct presence of lithium —five milliampères.

"The third trial was upon the person of an old man, suffering from acute and chronic uric-acid concretions. He was in an advanced stage of the ailment, and most of his joints were affected; the joints between the phalanges were almost obliterated. He immersed one hand in lithium chloride solution, the other in common salt solution, while a current from the one hundred and twenty volt electric-light circuit was employed through resistance to pass through his body. Measurements of the hand in the lithium chloride solution showed, after some twenty-five hours of total application, a distinct reduction of bulk. There was also considerable relief from pain, and the general condition of the patient was ameliorated. The current strength in his case was twenty milliampères (four times more than the previous healthy subject could stand with convenience)."

Mr. Kennelly also calls my attention to a pretty experiment recently described by Dr. Ehrmann to demonstrate the cataphoretic power of the anode:

Take two similar glass vessels, with zinc electrodes at the bottom, and filled with a very weak solution of methyl blue. Insert the hands, one in each, and cause ten to twenty milliampères to pass for five to ten minutes. The hand in the anode vessel will be covered with blue spots.

The earlier criticisms of medical men that there was no such thing as the anodal diffusion of drugs, must, in the face of such accumulating evidence, be entirely silenced. It is only one and a half years ago since, in the discussion of my paper, some who took part manifested entire incredulity. The far more vital criticism, however, that accuracy of dosage was impossible by this method of medication, has been until now unanswered. The hollow electrode of Munk with clay bottom, of Adamkiewicz with carbon bottom, and of myself with a membranous bottom, each has failed to determine properly the quantity of the medicament employed. But this is now no longer a valid argument against anodal diffusion, since by the means I have of late employed, exact dosage is simplicity itself.[1] It is only essential to possess a flat metal electrode, preferably but not necessarily of platinum (platinum is now almost as costly as gold), or tin. A nickel-plated surface will answer. This may be made of any size, round or square, convex or concave. A piece of tissue or filtering paper or linen is cut to fit over the metal surface. Upon it is placed, drop by drop, the solution of any drug to be used, and the electrode is then applied to the skin. There is then a thin capillary layer of the medicament in the paper disk between the electrode and the skin, and the quantity of the drug is known. The electrode made for me by Messrs. White and Bartlett, of this city, is round, flat, two or three centimetres in diameter, and is provided with a narrow, soft rubber rim at its edge, which, by its close approximation to the skin, prevents any loss of the solution by evaporation. In order to have drugs ready for use at any time, disks of paper to fit the electrode may be charged with aqueous or alcoholic solutions, and then allowed to dry, a drop or two of menstruum being added when they are to be used. Otto Boeddiker, pharmacist, 954 Sixth Avenue, of this city, is prepared to furnish anyone with medicated cataphoretic disks to fit the electrode, and has made for me satisfactory disks of menthol, cocaine, helleborin, strychnine, iodol, corrosive sublimate, aconitine, potassium iodide, imidosuccinate of mercury, and the chloride and benzoate of lithium.

As regards the current strength to be employed one must be guided by the patient's feelings. Anywhere from 5 to 20 milliampères may be used for from five to fifteen minutes. The stronger the current the shorter the duration of the séance. If one has no galvanometer he may use ten to thirty or more cells of any battery, Grenet, Lèclanchè, or chloride of silver.

Anodal Diffusion of Drugs.—The indications for the application of the method of anodal diffusion of drugs may be summarized as follows:

To Produce Local Anæsthesia for Neuralgias, Superficial Pains, and Cutaneous Operations.—With an additional experience of nearly two years in the frequent treatment of neuralgias of superficial nerves with ten to twenty per cent. solution of cocaine on the anode, I can only reiterate my conviction that it is the best means we have for relief of the pain without constitutional effects.

I have had no experience of the method in surgery, but I quote the following from a letter received from Dr. R. H. M. Dawbarn, June 10, 1889, which will merely serve as an instance of the successful employment of voltaic narcotism in a small operation:

"I have recently, since reading your article, tried this method upon a child's hand, requiring suture of a severed tendon. The injury was an old one, and there was no wound before I made my incision. The anæsthesia from ten per cent. cocaine upon the anode, continued with my chloride of silver battery (twelve cells) for ten minutes, was very satisfactory."

I have experimented with other local anæsthetics. Aconitia produces a deep analgesia, but it is accompanied with severe smarting around the edges of the anæsthe-

[1] New York Medical Journal, November 15, 1890.

tized area. A combination of cocaine with the aconitia prevents this hyperæsthesia. I was led by a note on helleborin[1] in a medical journal to make use of this alkaloid as a local anæsthetic. Three or four drops of a one per cent. solution of helleborin on the anode have brought about much more gratifying results than cocaine, a deeper and more lasting anæsthesia, and I have never noted constitutional effects. The latter need not be feared now that dosage has become accurate. At the same time I should advise caution in the employment of so powerful an alkaloid.

Both onabain and strophanthin[2] (Arnaud's, not Merck's) are strong local anæsthetics, and may be used with the anode in doses of $\frac{1}{250}$ of a grain or more. One or two drops of chloroform on a tissue-paper disk placed upon the anode will bring about a deep analgesia in a very short time, but will be followed later by vesication. When it is desirable to first anæsthetize and then counter-irritate, chloroform cataphoresis may be advisable, and will prove useful in some neuralgias.

A mild solution of carbolic acid may also be employed as a local anæsthetic and analgesic.

For Topical Medication in various Local Lesions, such as Tumors, Rheumatic, Gouty, and other Swellings, various Skin Diseases, Syphilides, etc.—For such cutaneous disorders as are commonly treated by painting with iodine, the use of some of the iodine preparations, such as potassium, sodium, or lithium iodide, iodol, or diluted tincture of iodine upon the anode is indicated.

For rheumatic and gouty swellings, solutions of the chloride, benzoate, or citrate of lithium, all very soluble salts, should be employed with the anode. Among mercurial remedies the imidosuccinate and bichloride of mercury are well adapted for cataphoretic purposes.

The rhinologist and laryngologist will find the method particularly adapted to the treatment of many difficulties of the upper air-passages which may require the application of anæsthetics, astringents, or antiseptics.

For Electro-cataphoretic Baths for General Purposes.—There would seem to be considerable usefulness in the method as applied to mineral baths. Although Gärtner has been at great pains to invent a particular kind of bath-tub with two compartments for electrical purposes, it is not essential to have any such arrangement. By making an ordinary bath the anode, the hands may close the circuit by grasping a cathode suspended just above the bath. Thus almost the whole surface of the body may be subjected to the anodal diffusion of the therapeutic agent dissolved in the bath. Outside of tonic, stimulating, and alterative, such as are found at health resorts, cataphoretic baths of iodide of potash might prove useful in cases of lead poisoning, etc.

The Use of Cataphoresis for Diagnostic Purposes.—In the discussion which followed the reading of my first paper upon this subject, Dr. Starr called attention to the possible usefulness of cocaine cataphoresis in diagnosis. Thus, if a pain were complained of, for instance, in some part of the trigeminus, it should disappear under this treatment. If it did not, the lesion could be localized further back, or it might lead to the conclusion that it was a hysterical pain. I had myself an interesting example of its usefulness for this purpose some time ago. I was called in consultation to see a lady who had been suffering for months with a rather superficial but excruciating pain in the knee following slight trauma. The knee was swollen from blistering, the limb was rigid, the patient sleepless from pain, and anxious to have the leg amputated. The spot upon which I placed the anode with cocaine was so hyperæsthetic that the slightest touch made her wince with pain. Her eyes being closed, I stuck a pin in the part after a few minutes, which she did not notice. When she opened her eyes, the electrode having been removed, I touched the anæsthetic part with my finger, and she winced with pain the same as before. Although the limb was, I believe, subsequently amputated, my diagnosis of a hysterical knee-joint was amply corroborated by microscopical examination.

In view of all the facts which I have adduced in this brief paper, there can be no doubt that the anodal diffusion of drugs is destined to far wider application than it has as yet enjoyed, and that the general practitioner and the specialist alike will find the procedure increasingly useful as a practical therapeutic measure. To close with a quotation from an editorial in the *New York Medical Journal*, December 28, 1889, it is a method that "opens a way not otherwise attainable for influencing tissue metabolism and for changing morbid nutritive processes by sending the drugs into direct and immediate contact with diseased parts through a force which in itself must greatly enhance their active medicinal properties."

HYSTERO-NEUROSIS AND MELANCHOLIA CURED BY TRACHELORRHAPHY.

By FRANK CHURCHILL, M.D.,
NEW YORK.

The patient, Mrs. B——, twenty-eight years of age, has been married six years; has had no miscarriage, and but one child, born June, 1888, by instrumental delivery. She was well and strong two weeks after confinement, and continued so till September, 1889, when she weaned the baby. Then, as usual, the menses began to appear, and she began to have sleepless nights; after a few weeks she slept little or none at night, being nervous and wakeful. She continued in this condition all winter, gradually losing health and strength, and yet was able to do most of her housework till the following April, when she began to neglect her housework and the care of her baby, and became absent-minded, silent, and despondent.

About May 1st she received a telegram announcing the death of a friend by suicide. This sudden and awful news caused severe mental shock, and produced such alarming increase of her symptoms that a physician was at once consulted.

From this time on she became more gloomy and despondent, neglected her housework entirely, and had constant headache.

She was afraid to be alone, yet would sit silent, staring vacantly, in the presence of her friends. At times she would break out fiercely, saying, "You stop talking about that!" The subject of conversation would be changed and she would lapse into silence again. Questions repeatedly asked would finally elicit a nod or shake of the head, and occasionally a monosyllabic answer.

She was under constant medical treatment from May to August, but her condition remained much the same. When she was brought to me, August 5th, she was clearly a victim of melancholia. She had delusions of sight and hearing; the common sights of the streets and every-day topics of conversation would conjure up visions and thoughts that distressed her greatly.

She also had hallucinations; "people were troubling her all the time," and she "felt something urging her to do this and that, like killing her baby."

After making a careful physical examination, the only lesion I could find was a bilateral laceration of the cervix. I told her husband that her condition might be due to the laceration; that I would first endeavor to restore her health by medicinal treatment and if that failed I would operate.

Sulphonal restored her sleep perfectly, a few simple remedies improved her appetite and regulated her bowels, so that by the first of September she had gained flesh and strength, and said she felt strong and well so far as her body was concerned, but had the same trouble with her mind. Her friends assured me that her mental condition and actions were just the same.

After seven weeks of this improved physical condition,

the mental condition being still the same, I operated, October 16th.

The third day after the operation, when she had rallied a little, it was evident that a mental change was taking place, and at the end of a week her sister, who is a nurse, and who was in constant attendance, said: "Why, doctor, her mind is all right now, there is a complete change," which was quite true. She made a good recovery, and is now perfectly sane.

In conclusion, the following facts are significant: She was perfectly well until the uterus took up again its function of menstruation, and her sickness dates from that time.

Her condition remained the same in spite of medication till the lacerated cervix was repaired, and her recovery dates from the day of the operation.

I believe that the irritation of the lacerated cervix, which, while menstruation was in abeyance, was nil, became, when that function was re-established, the *fons et origo* of her maladies.

Clinical Department.

PRACTICAL NOTES ON THE PROPHYLAXIS AND TREATMENT OF DIPHTHERIA.

By F. H. PECK, M.D.,

CLINTON, N. Y.

The perusal of Professor Löffler's *résumé* on the prophylaxis of diphtheria, in the Medical Record of December 13th, leads me to supplement it with a description of a method of immediate prophylaxis for the benefit of those already exposed to the contagion, and where isolation is impracticable; with a brief account of a treatment which I have found very efficacious for the cure of the disease.

During the past winter I attended fifty-two cases of diphtheria. The type of the disease was very malignant, and as but three of my cases terminated fatally, I subjoin my method of local antiseptic treatment, in the hope it may be of use to the profession.

On being called to a case of diphtheria, besides insisting on the enforcement of ordinary sanitary rules—including the isolation of the patient—where practicable, I direct all persons who have been exposed to the contagion to use four times in each twenty-four hours a one per cent. solution of creolin as a gargle. In the case of infants too young to gargle, I advise the use of the solution with a swab, or as a spray. Most of my cases have occurred among the poorer class, where isolation was impossible; but though the unaffected children spent most of their time in the same room with those who were ill, I have never had a second case develop in a family where the above measures were carried out.

In my early treatment of the disease, I employed the method advocated by Oatman, of Nyack, in the *Annual of the Universal Medical Sciences*, of 1888; but I found the solution of mercuric bichloride advised by him (1 to 3840) inadequate to destroy the exudation, and my three fatal cases occurred before I had gained sufficient temerity to use the strong solutions I have since employed with invariable success.

The solutions I now use are of corrosive sublimate, varying in strength from 1 to 100 to 1 to 50, according to the age of the patient and the necessities of the case. With young children, and in mild cases of the disease, I use the weaker solution, and in every case, as the exudate disappears, I decrease the strength of the solution. This solution I label "Poison," and direct to be used as follows: Make swabs by wrapping a small tuft of absorbent cotton tightly about the small end of a tapering stick of wood, one-eighth of an inch in diameter at small end, and six or seven inches long. The cotton-wrapped part of the swab should not exceed one-quarter of an inch in diameter. Saturate the swab with the bichloride solution, and rub thoroughly over all exudation on tonsils and pharynx, making firm pressure, and giving a rotary or twisting motion to the swab to facilitate the removal of the exudate. Repeat the operation every two hours, day and night, in severe, and every four hours in mild, cases. Burn the swab immediately after using, and employ a new one for every fresh application.

When the exudation invades the nasal passages I direct them to be douched every four hours with a one per cent. solution of creolin. Internally I use iron, stimulants, etc., as the symptoms may require. I claim for this method of treatment: 1. Its efficacy. The majority of cases show marked improvement within twenty-four hours, and are convalescent within a week. 2. Its freedom from danger. I have never seen an instance of intestinal disturbance or stomatitis among my cases. Constipation, requiring occasional laxatives, has been the rule, and if the swabs be tightly wrapped and made sufficiently small, they will not absorb to exceed three or four minims of the solution, and will retain most of that after swabbing. 3. Its simplicity. In but one of my cases have the services of a trained nurse been available, and members of the family have, after instruction, put the method in execution. 4. This method combines the advantages of the local and internal use of the bichloride, as a small amount of the solution must necessarily be absorbed at each application.

IMPERFORATE HYMEN.

By FREDERICK H. WIGGIN, M.D.,

NEW YORK.

The following case appears to be of interest, taken in connection with the recent reports of similar cases in the Medical Record. On August 11, 1888, I was called to see a girl, J. C——, fifteen years of age, whom I found in great pain, and who gave the following history:

For the previous year about every four weeks she had had more or less pain in the pelvic region (her mother stated that she had never menstruated), but during the intervals she had been perfectly well. The pains had gradually increased in severity and duration till, for several weeks previous to my having been called, they had been constant, and for some time she had been unable to sit down.

On examination a small tumor was found in the hypogastric region and on attempting to make a vaginal examination I found a fluctuating tumor projecting from the vulva about the size of an orange, and of course there was no opening in the hymen.

On making an incision three pints of dark, thick, odorless blood was evacuated. The patient did not have any pain during the contraction of the uterus. I washed out the vagina with a 1 to 4,000 bichloride solution. Although I requested her mother to keep her in bed till I saw her the following day, when I arrived I found her at work. Her temperature and pulse were normal and she had no further trouble.

Hyperalimentation in Acute Delirium.—Dr. G. Guicciardi has obtained in the treatment of acute delirium less unfavorable results than one usually observes in this disease. He only lost (out of eleven cases) four by death, while five completely recovered, and two became weak-minded. The treatment adopted by him consisted in isolation, removal of all sources of irritation, protracted lukewarm baths, with the simultaneous application of ice-bladders to the head, and a few leeches to the mastoid process, as well as in revulsion to the intestine and ergotine injections. But he places a still greater emphasis upon the richest possible feeding, and indeed by methodic feeding, by means of the sound, every three to four hours with ten ounces of the most nourishing fluid food.

Progress of Medical Science.

Euphorine.—Dr. Sansoni has made a number of observations on the action of euphorine in disease. Professor Giacoso has given this name to phenyl-urethan,

$$CO\begin{matrix}OC_2H_5\\NH(C_6H_5)\end{matrix},$$

a new substance derived from aniline. It is a white, crystalline powder, with faint aromatic odor and slight taste, almost insoluble in water, but quite soluble in weak alcohol. Sansoni first tested the antipyretic effect of euphorine. In fever due to a large number of causes the temperature fell quickly within an hour; the fall reached its maximum usually in three hours, and lasted for five to seven hours, but sometimes not so long, and at other times longer. The subsequent rise of temperature was usually sudden and accompanied by rigors. Its antipyretic action is often greater in certain individuals than in others, and hence it is advisable to begin with small doses. Doses of fifteen to twenty grains in twenty-four hours can generally be taken without bad results. It is best to begin with a dose of three grains. In rheumatism, fifteen to thirty grains daily caused disappearance of the pain, swelling, and fever. In chronic cases the good results were slight. In a few cases euphorine acted well as an analgesic, but on the whole the success must be considered small. In chronic ulcers and in ophthalmia the powder proved itself a better antiseptic than any other which the author had tried. On the whole, as an antipyretic, antirheumatic, and analgesic, euphorine seems to be inferior to many older remedies of the same nature, and unless future experience bears out the high character given to it by Sansoni as an antipyretic, there is little likelihood of its ever becoming a useful drug.—*The British Medical Journal.*

The disease is tedious in its course, but the patients ultimately recover.

In the matter of treatment it was found that most of the patients were over-fed, and that a plain and liberal, but not excessive, diet was indicated. Locally, glycerine of borax with oxychloride of bismuth and morphine may be brushed over the whole throat three or four times daily, or instead of morphine, cocaine may be used; but in this case great care must be taken.

Internally, quinine, iron, arsenic, zinc, and belladonna, are recommended.

The disease which Dr. Clark describes belongs to the class known by French writers under the name of convulsive tic, and called sometimes also a form of chronic chorea. Cases of this kind have been seen and described by American writers.

RHEUMATIC ARTHRITIS AND RHEUMATOID ARTHRITIS.

We follow with much interest the attempts of clinicians and pathologists to show the difference between chronic rheumatic arthritis and rheumatoid arthritis. The conspicuous failures of the past do not discourage writers, and have not in particularly discouraged Mr. Hugh Lane, of Bath, England, who publishes a monograph entitled "Differentiation in the Rheumatic Diseases." Mr. Lane's present brochure is condensed from a work by himself and Mr. Charles T. Griffiths on the same subject, which work is h[illegible]

studied the former type among children of the age of from eleven to sixteen months (*The Lancet*). A great many of the patients had been brought up on the bottle, having been fed on unsuitable food, causing distention of the abdomen or stomach, or occasionally enlargement of the liver, or intestinal disorders, accompanied by vomiting or diarrhœa. He believes this special form of albuminuria to be of an infectious character, and traces it back pathogenetically to certain toxic substances which are generated by abnormal fermentation in the bowels. These substances are absorbed by the bowels and pass to some extent into the kidneys. They produce congestion in the renal tissue, which may lead to inflammation of the kidneys. One of Dr. Seyournet's little patients had scarlet fever twenty-two days after convalescence from this albuminuria. It is evident from this fact that it was not scarlatinal albuminuria. It was usually accompanied by anuria, whereby the congested condition of the kidneys was intensified. With some of the patients the daily evacuation of urine was only half an ounce. In one case the patient passed no urine for more than forty-eight hours. Notwithstanding this, no uræmic symptoms appeared. It was in most cases only the anuria which led to the urine being examined for albumin. The result of the examination in each case was positive. A strongly marked feature of this disease is the œdema of the feet, sometimes also of the hands and of the eyelids and face, but the latter were not always affected. The quantity of albumin varied from a drachm to ten drachms per diem. The duration of the disease was from two to four weeks. The treatment consisted in giving milk, which in some cases was mixed with lime-water. Where there was vomiting, gentle aperients, such as castor oil or calomel, were given; salicylate of bismuth was employed in order to disinfect the bowels as much as possible. Systematic massage of the lumbar regions was also employed in order to relieve the congestion of the kidneys.

Pes Planus.—Mr. A. G. Miller, one of the surgeons at the Royal Infirmary, Edinburgh, emphasizes the point of differential diagnosis between pes planus and talipes valgus. His contention is certainly a correct one. In the early stage of flat-foot pes planus is alone present; while in the latter, or pronounced condition, talipes valgus results of necessity from the subsidence of the inner side of the foot, and the consequent inability of the ball of the great toe to play its part as the inner support of the superimposed weight of the body. Again, Mr. Miller draws attention to the fact that genu valgum and flat-foot are by no means constantly associated. In proof of this we have recently seen a marked case of genu valgum (so bad as to require a double osteotomy) where the patient's foot was actually in the position of varus; and the boots were notably worn down at the outer edge of both soles and uppers. We demur to the use of the words supination and pronation as applied to foot movements.

Mr. Miller's meaning is more easily caught by speaking of the inversion or eversion of the sole. His reiteration of the value of the wedge-shaped sole (advocated by Professor Miller in 1846) is worthy of note; for its utility is demonstrated both by the anatomical adjustment of the astragalus and by the evidence that many people suffering from commencing flat-foot find relief by voluntarily adopting it as a means for the relief of pain. The treatments also suggested by rest, massage, tonics, and regulated exercise are excellent. As yet Mr. Miller has not had occasion to perform any cutting operation for the relief of flat-foot. We have seen at one of the London hospitals intractable cases treated by osteotomy. The impression formed by observation of these cases was that certain aggravated types of flat foot do occur which have resisted all other modes of treatment, and that the results gained by a free resection of the tarsal bones have been satisfactory to the sufferers by restoring symmetry to the foot, and by the complete relief from constant and intolerable pain on walking.—*The Lancet.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, January 31, 1891.

IMPURE DRUGS.

THE last report of the New York State Board of Health shows that, while the sale of impure drugs is decreasing, it is yet lamentably large. During the year 1889, 807 samples of drugs were bought in the larger towns and cities of the State (excepting New York and Brooklyn) and subjected to analysis. The results are startling. Only 410 samples (50.8 per cent.) were up to the pharmacopœial standard, while 330 of the samples (40.8 per cent.) were totally deficient, by being either falsified, adulterated, decomposed, too strong, or too weak. The remaining 67 samples were of "fair quality." In some details the results of the analysis were as follows: Dilute acetic acid, 40 samples examined; 9 good, 6 fair, 19 inferior, and 6 of excessive strength; this is of unusual importance because of its use in the manufacture of spirits of mindererus. Dilute nitric acid, 4 samples: 1 good, 3 excessive strength. Dilute sulphuric acid, 53 samples: 9 excessive strength. Hydrobromic acid, 38 samples: 6 inferior and 6 excessive strength. Saffron, 20 samples: 2 good, 1 fair, 17 inferior. Compound spirits of ether (Hoffman's anodyne), 47 samples: 4 good, 4 fair, and 39 inferior. Stronger ether, 66 samples: 40 good, 4 fair, and 22 inferior. Precipitated sulphur, 25 samples: 6 good, 2 inferior, and 17 inferior. Besides these, inferior samples of oxalate of cerium, chloral, and chloroform were found. 115 samples of cream of tartar were bought at grocery stores, and of these only 30 were good preparations, 6 being fair, and 79 "clearly adulterated or falsified." Also there were examined 275 samples of alkaloidal preparations, including sulphate of quinine, citrate of iron and quinine, sulphate of morphine, and tincture of opium. Of these 177 were good, 13 of fair quality only, and 85, or 30 per cent., were "unreasonably deficient."

The object of the work is not so much to determine the proportion of adulterated to pure drugs on the market as to expose actual adulteration, sophistication, and carelessness; to inform the public and to caution dealers. Consequently a great variety of drugs was not purchased, and only those were chosen that were likely to be adulterated. But though the frightful showing of the figures above does not represent the actual proportion of impure drugs sold, it shows the deplorable chance to which a physician in prescribing is subjected. One inclined to be facetious might remark, that, what with the difficulty of making a correct diagnosis, the furore and trouble the germs are creating, the chance of getting impure medicine, and the awful weather, it is a wonder that any of our patients live.

The practical value of these analyses comes from the fact that notices are sent to dealers from whom impure drugs are bought, notifying them of the impurities. Rarely does a second notice have to be sent and the standard of preparations is being gradually raised to that of the Pharmacopœia. The law is adequate to its purposes. It simply needs enforcement. After one or two or three warnings the penalties laid down should be applied. In the examination of alkaloidal preparations the bulk of attention was very properly paid to quinine preparations, as the report states that some druggists sell as many as two hundred thousand two-grain pills annually, and that fifty thousand is the estimate made of the average number sold by a druggist doing an ordinary business.

THE BARKING COUGH OF PUBERTY.

WE have commented before upon the remarkable resourcefulness of Sir Andrew Clark, who every year, from the stores of his experience, furnishes either some new disease or at least some contribution to nosology.

In a paper recently read before the Medical Society of London, Sir Andrew described a disorder which he terms "the barking cough of puberty," or cynobex hebetis. This he considers to have such peculiar and distinctive features as to entitle it to be classed among the distinct

a great pain, and who gave the following history:

For the previous year about every four weeks she had had more or less pain in the pelvic region (her mother stated that she had never menstruated), but during the intervals she had been perfectly well. The pains had gradually increased in severity and duration till, for several weeks previous to my having been called, they had been constant, and for some time she had been unable to sit down.

On examination a small tumor was found in the hypogastric region and on attempting to make a vaginal examination I found a fluctuating tumor projecting from the vulva about the size of an orange, and of course there was no opening in the hymen.

On making an incision three pints of dark, thick, odorless blood was evacuated. The patient did not have any pain during the contraction of the uterus. I washed out the vagina with a 1 to 4,000 bichloride solution. Although I requested her mother to keep her in bed till I saw her the following day, when I arrived I found her at work. Her temperature and pulse were normal and she had no further trouble.

Hyperalimentation in Acute Delirium.—Dr. G. Guicciardi has obtained in the treatment of acute delirium less unfavorable results than one usually observes in this disease. He only lost (out of eleven cases) four by death, while five completely recovered, and two became weak-minded. The treatment adopted by him consisted in isolation, removal of all sources of irritation, protracted lukewarm baths, with the simultaneous application of ice-bladders to the head, and a few leeches to the mastoid process, as well as in revulsion to the intestine and ergotine injections. But he places a still greater empha-

"The malady of this patient lasted over two months, and then slowly subsided."

Sir Andrew reports four severe cases similar to the

foregoing, but adds that it often occurs in milder and less typical forms. He finds but brief reference to the subject in literature, but thinks it has been recognized and described, and cannot be called a new disease. Still, as a clinically distinct disorder, and one not extremely rare, he affirms that it has not received its share of attention. The disease is recognized in Sir Morell Mackenzie's "Diseases of the Throat and Nose," but the description differs somewhat from that given by Dr. Clark. There it is described as occurring in young girls between sixteen and twenty, of having been met with in boys between fourteen and sixteen, and of having been seen several times in children between five and fourteen years of age.

With regard to the nature of the disease, Dr. Clark refers to the irritable condition of the nervous system at the time of puberty, and adds: "When, furthermore, we remember that for the most part the family and personal history of the patient is nervous; that no local adequate changes are to be found in the pharynx, in the larynx, or in the lungs; that the cough and other disturbances of the respiratory movements are rhythmic and paroxysmal; that no structural degenerations follow in the wake of the malady; and that it disappears with, or shortly after, the complete evolution of sex—we cannot doubt, at least I think, we cannot justly doubt—that this convulsion or barking cough of puberty (cynobex hebetis, pubertatis tussis caninalis) is a malady of nervous origin, character, course, and issues. But in how far the inborn changes which engender it are central, or in how far peripheral, and to what extent they are modified or controlled by extrinsic influences, I am at present unable to determine."

The disease is tedious in its course, but the patients ultimately recover.

In the matter of treatment it was found that most of the patients were over-fed, and that a plain and liberal, but not excessive, diet was indicated. Locally, glycerine of borax with oxychloride of bismuth and morphine may be brushed over the whole throat three or four times daily, or instead of morphine, cocaine may be used; but in this case great care must be taken.

Internally, quinine, iron, arsenic, zinc, and belladonna, are recommended.

The disease which Dr. Clark describes belongs to the class known by French writers under the name of convulsive tic, and called sometimes also a form of chronic chorea. Cases of this kind have been seen and described by American writers.

RHEUMATIC ARTHRITIS AND RHEUMATOID ARTHRITIS.

We follow with much interest the attempts of clinicians and pathologists to show the difference between chronic rheumatic arthritis and rheumatoid arthritis. The conspicuous failures of the past do not discourage writers, and have not in particularly discouraged Mr. Hugh Lane, of Bath, England, who publishes a monograph entitled "Differentiation in the Rheumatic Diseases." Mr. Lane's present brochure is condensed from a work by himself and Mr. Charles T. Griffiths on the same subject, which work is based upon experiences with over three thousand cases. The author ought to be able, therefore, to speak with some authority.

He tells us in the beginning that rheumatism "is increasing with terrible frequency among the young," and he urges the necessity of prevention and early interference with the disease.

Mr. Lane finds that there are two distinct diseases among the victims of what is popularly called chronic rheumatism. He calls them rheumatic arthritis and rheumatoid arthritis.

The patient with rheumatoid arthritis presents a peculiar pallor, and the family or personal history shows a "strumous" taint, whatever that may be. The joints are crippled and deformed, with distinct muscular atrophy. If the fingers are affected the swellings have a strong inclination to be spindle-shaped. The proximal phalangeal joints of the second finger are favorite points of attack. There is more thickening of the capsule and more effusion. General weakness, anæmia, emaciation, loss of appetite, lassitude, and various neuroses accompany rheumatoid arthritis. In advanced conditions of the joint trouble there is an osteo-arthritis.

Mr. Lane thinks that the difference between rheumatic and rheumatoid arthritis is about as wide as it can possibly be. Yet we regret to say that he has quite failed to show in what respect they are so fundamentally apart. The attempt to differentiate the diseases by clinical facts alone is most unsatisfactory. Pathology is of some help, for it shows us that rheumatoid arthritis is primarily more of a distinctive and degenerative process, while rheumatic arthritis is more irritative and inflammatory in character. But, after all, we are still much in the dark, and we hope that Mr. Lane and others will try again to solve the problem.

THE PATHOLOGY OF EMPYEMA.

It is quite generally believed, at the present time, that suppuration is due to the action of microbes. Dr. Henry T. Bewley, of Dublin (*The Dublin Journal of Medical Science*), is, therefore, right in stating that empyema is due to the entrance of pus-producing organisms into the pleural cavity. These micro-organisms have been looked for and found by a large number of observers. Serous pleural effusions are, however, usually free from organisms. Fränkel states that if micro-organisms are found in serous fluids removed by exploratory puncture, an empyema already exists, the pus-corpuscles, through their higher specific gravity, having sunk to the bottom, and left a layer of serum above.

Dr. Bewley says further that, according to their pathology, we may divide cases of empyema into several classes. The way in which the bacteria effect an entrance into the pleural sac is in some cases plain and evident; in other cases it is doubtful.

First, there are cases of empyema which are due to the introduction of ordinary pus-producing organisms, either through the chest-wall or from the lung into a healthy pleural sac, or into a previously existing serous effusion; as when a penetrating wound of the chest-wall is received, when a pulmonary abscess or an area of gangrene in the lung comes to communicate with the pleural cavity, or when a septic exploring needle is introduced into a serous effusion.

Secondly, some cases of empyema occur in immediate

connection with croupous pneumonia, and are caused by the organism which is believed to cause many cases of pneumonia—the so-called pneumococcus of Fränkel. Out of twelve cases of empyema which this observer examined, in three he could not find in the pus any other organism than the pneumococcus. He remarks that he has found the prognosis, in cases of empyema due to the pneumococcus, to be better than in those which are caused by the ordinary pus-producing micrococci.

A third group consists of those cases in which the infective virus is the tubercle bacillus. In these cases tuberculosis of the lung exists, and the bacilli make their way through a hole in the pulmonary pleura. In some cases the rent in the lung is manifest and large, as when a phthisical cavity bursts into the pleural sac, giving rise to a pyopneumothorax; in other cases minute perforations occur in the lung, through which a minute particle of tubercular matter gets into the pleural sac. In these latter cases a tuberculous empyema develops without any pneumothorax.

In a fourth class of cases, those in which a serous effusion becomes purulent without apparent cause, the organisms probably get into the pleural sac by way of the blood- and lymph-channels. To explain such cases it is assumed that under various conditions, especially when the general health is not good, different kinds of pathogenic organisms find their way into the tissues of the body, are carried about by the blood and lymph, and, if they find in any part of the body conditions suitable for their growth, develop and multiply, and cause suppuration.

A fifth variety of empyema occurs in pyæmia. In this disease enormous numbers of micro-organisms exist in the body; they form emboli, which block up small blood-vessels, and give rise to secondary abscesses. The pleura may be affected, and a pyæmic empyema ensue. These cases differ from the last mentioned, in that in these pyæmic cases the organisms probably exist in the blood in far greater numbers, and possibly possess greater virulence.

So far from being a single disease, with a uniform origin and single exciting cause, empyema, in the light of modern pathology, must be regarded as symptomatic of quite a number of morbid conditions. Fortunately, whatever its origin, the treatment indicated is always the same, *i.e.*, to remove the pus, and prevent its reaccumulation by that method which is least liable to prove injurious to the general condition of the patient.

THE LAW AND THE WET-NURSE.

A curious case came before the city court last week, and one with a more than curious termination. A gentleman discharged a wet-nurse because she went out at night and, on this and other grounds, was not satisfactory to him. The nurse brought suit for breach of contract, and asserted that as long as she supplied the infant with good milk, the father had no right to dismiss her. A pair of healthy-looking twins were produced in court as evidence of the superior lactogenetic capacity of the wet-nurse, whatever might be the irregularity of her habits or the delinquencies of her morals. The jury rendered a verdict for the plaintiff, and awarded her the full amount of her salary according to her alleged contract.

We are not sufficiently versed in its mysteries to say that this was not good law; but it must strike those who have ever had dealings with wet-nurses as a most grotesque miscarriage of justice. In this city there are two things which are usually done with wet-nurses: they are first engaged, and they are next discharged—the two events being as a rule in very close sequence. If the Court is going to take away the privilege of discharging wet-nurses, the milkless mother and infant will have an unfortunate time of it. We very much doubt if any of our city readers, at least, can recall a case in which the wet-nurse's first engagement stayed out the period of lactation. The moral of the case just cited will be that fathers must make no contracts, written or implied, to keep the wet-nurse till the babe is weaned.

The wet-nurse is at best a trial and vexation of spirit; and there is an increasing tendency to put the infant on the bottle, if the mother fails to supply enough good milk.

THE SALOONS AND THE HOSPITAL SUNDAY ASSOCIATION.

There is a popular impression that drinking is a convivial pastime which warms the soul, expands the feelings, and kindles sentiments of good fellowship and generosity. This impression, we should add, is a popular one among the drinking classes only; it does not prevail among prohibitionists, and is not set forth in the *American Journal of Inebriety*.

A study of the returns of the Hospital Saturday and Sunday Fund does not support the impressions favorable to the generosity of the bibulous. There have been, up to date of writing, $47,310.00 received from all sources by the Association. Of this sum $591 was received from various cafés and bars about town. The sums ranged from $10 to about $40. At one well known café, where thousands of dollars are reputed to be taken in daily for drinks, the amount contributed to the fund was $20.72. The Hospital Association gets over $30,000 from the churches, $500 from the saloons, and nothing from the Presbyterians. Here is an opportunity for the moralizer.

THE NEW YORK COUNTY MEDICAL SOCIETY.

The minutes of the County Medical Society, which have just been published, show that this organization is quietly yet energetically doing a great deal of good work, both for our profession and the community. Without the prestige of an elaborate home and a library like the Academy, the County Society nevertheless has its following of loyal members and wise executive officers. The society has the largest membership of any local society in the State, and probably in the country, and it consequently represents the great medical democracy and looks out faithfully for its interests. Aside from much excellent scientific work, the County Society has been the pioneer in the war against quackery, and in enforcing the medical laws directed against this class.

In the past year it spent $2,357.95 for legal services. The report of the Society's counsel, Mr. Purrington, shows that 159 cases were investigated, 20 arrests were made, 11 cases tried, 10 convicted; while the gross amount of fines imposed was $850. Among cases still pending

are those of Irish, John H. Woodbury, Wimpleberg, Guggenheim, Batt, Fulda, and Allen. The County Society was the first to secure the conviction of a person for using the letters M.D. appended to the name without authority. The advice of its counsel has also been of much service to the Board of Regents during the recent somewhat perplexing medical legislation.

The Society has done useful work also in directing attention to the need of public baths, and to the deficiencies in the public schools.

It publishes a medical directory, whose contents are not modified by the personal bias of its editor, but accurately represent the medical profession of the county and city. Lastly, and not least in the opinion of many, it has introduced at its meetings the feature of a collation, a kind of aftermath of sandwiches and colloquial science.

MEDICINE AND MONEY.

We referred a short time ago to the fact that the free gift by Koch of his discovery to humankind ought to produce upon the secular and commercial mind a favorable impression as to medical methods and medical ethics. There is evidence that it has had this effect.

The New York *Tribune* says: "Physicians are almost the only members of the community who do not make money out of their important discoveries. It is a point of honor among them to allow the whole world to profit by their researches when they find a new remedy for widespread disease. Their reward is in the benefit which the sick and helpless receive, and in the gratitude, which should not be stinted, of the community at large."

The Minneapolis *Tribune* follows in the same line: "The greatest and best medical and surgical discoveries have been free gifts to suffering humanity the moment their value has been demonstrated. The use of anæsthetics, the principle of vaccination, new or improved operations in surgery, new drugs and methods of treatment, have invariably become the common property of the faculty from the hour of their discovery."

We see so much in public print directed against the courtesies and the ethics of our profession that it is refreshing to hear kind words. Medical men are not angels; they are in fact very human creatures with much hard work to do and often many mouths to feed; but there is a strain of benevolence in all their daily work. From the beginning they are taught a doctrine of helpfulness to others, and are made to think that their life-work should not be one in which every service must receive its pecuniary reward. Koch's discovery will not be valueless if it only impresses on the profession and the laity these facts.

New York County Medical Association.—At the annual meeting of the New York County Medical Association, held January 19th, the following officers were elected: *President*—Dr. S. B. W. McLeod; *Vice-President*—Dr. William T. White; *Recording Secretary*—Dr. P. B. Porter; *Corresponding and Statistical Secretary*—Dr. A. D. Ruggles; *Treasurer*—Dr. John H. Hinton; *Members of the Executive Committee*—Drs. Edward Sanders, N. J. Hepburn, William B. De Garmo, and George T. Harrison. The membership of the Association now amounts to five hundred and eighty-three.

News of the Week.

Obstetric Section, New York Academy of Medicine.—At the annual election of officers for the Section on Obstetrics and Gynecology of the New York Academy of Medicine, January 22d, Dr. Egbert H. Grandin was re-elected Chairman, and Dr. Irwin H. Hance, Secretary for the ensuing year.

Railway Sanitation.—An ordinance has been passed in Indiana which compels all railroad companies to put storm doors on all railroad coaches and street cars for the carriage of passengers, to keep the temperature from sixty-eight to seventy in the cars, and to furnish spittoons partly filled with a solution of bichloride of mercury, for the use of persons suffering from chronic cough and expectoration.

Joseph Parrish, M.D., formerly Superintendent of the Pennsylvania Training School for Feeble-minded Children, President of the American Association for the Cure of Inebriates, died at Burlington, N. J., January 15th, aged seventy-two.

Dr. W. J. McClure, Health Officer of York, Pa., died January 24th, aged fifty-two. He was well known throughout the State, having been a member of the Legislature from Adams County, in 1878.

The Cost of the Present Coroner System.—The cost to the county of Westchester last year for coroners' inquests and doctors' fees for medical examinations was $10,427.54 This fact is announced in the press under the head of "big doctor's bills." As a matter of fact, it s not the doctors but the politicians who are, as a rule, coroners, and get the big fees.

A Death from Hydrophobia occurred in this city on January 23d. He was bitten on the lip six weeks before, by a dog at Arlington, N. J.

The American Electro-Therapeutic Association was organized January 22d, at the New York Academy of Medicine, by the election of the following officers: *President*—Dr. G. Betton Massey, of Philadelphia; *Vice-Presidents*—Drs. W. J. Morton and A. H. Goelet, of New York; *Secretary*—Dr. William H. Walling, of Philadelphia; *Treasurer*—Dr. George H. Rohé, of Baltimore; *Executive Council*—Drs. H. R. Bigelow, of Philadelphia, F. H. Martin, of Chicago, William H. Hutchinson, of Providence, R. I., and C. D. Palmer, of Cincinnati.

Medical Teaching in Portugal.—A new medical school, on a scale of equipment adapted to the needs of modern medical education, is about to be erected in Lisbon, at an estimated cost of 400 contos of reis. It has also been decided to make better provision for clinical teaching by the establishment in the Portuguese capital of a "Policlinic," somewhat on the model of the new Policlinico Umberto I., at Rome.

An Imperial Wedding Present.—Dr. F. Bramann, Professor of Surgery in the University of Halle, who, in the absence of Professor v. Bergmann, performed tracheotomy on the late Emperor Frederick, was married recently, and received on the occasion a patent of hereditary nobility as a wedding present from the reigning Kaiser.

To Reorganize the Morgue.—A committee of the Medico-Legal Society, consisting of Messrs. Clark Bell, S. M. Ehrlich, H. A. Mott, Jr., and Dr. M. J. B. Messemer, and P. L. Donlin, has offered the following sensible suggestions for the consideration of the authorities: "That the basis of the proper organization of the morgue should be substantially that adopted in the city of Paris, France; that the chief be selected from one of the ablest physicians in the city, thoroughly informed on all questions of pathology and toxicology, and his staff be composed of specialists in every branch of scientific research, so as to be able to conduct autopsies, to insure the detection of crime, in case it has been committed, even in the most obscure cases; and that the salary of the chief should be the highest salary paid to any medical man in the city, and it should be sufficient to command the services of the ablest talent in the profession of chemistry and medicine, and especially such as have distinguished themselves in pathological studies and morbid anatomy."

"Parataloid."—It has been stated that Koch suggests the above name for the "lymph," which he first compounded. The word is presumably derived from *παρά*, beside, alongside of, and *τάλᾶς*, suffering.

Medical Curiosities.—Among the curious cases which came under our notice, says a correspondent of *The China Missionary Meaical Journal*, is the following one of protracted labor, where the father of the woman, seeing that both mother and child were in danger, seized a sharp iron hook, resembling those on which the butchers hang dressed beef, but here used on the native steelyard. Introducing this into the scalp of the child, he succeeded in saving both mother and child. Nearly the whole scalp was detached in three places from the skull. The father walked twelve miles to the hospital with the child in his arms. The wound was sutured with silver wire, and today the infant is a vigorous boy.

An Epidemic of Rabies is said to prevail in the neighborhood of Reading, Pa. Three persons have been bitten by dogs presumably rabid.

Medical Legislation in Connecticut.—A number of medical men met at Hartford, Conn., on January 27th, in order to complete the draft of a medical practice act.

Parataloid and Poetry.— Dr. San Martin, a Spanish physician, cites the case of a man who a short time ago was exhibited at a meeting of medical men as a "bacillary museum," and who, after seven injections of parataloid, was so greatly improved (notably in respect of the discharge from a number of suppurating glands), that he celebrates the virtues of the *linfa maravillosa* and the glory of its "immortal and illustrious" discoverer in a dithyrambic ode addressed to Dr. San Martin. In a case of hip-joint disease considered to be probably too far advanced for operation, the improvement, both local and general, was also very marked.

The Ricord Prize.—The French Academy of Medicine has been authorized by the Minister of Public Instruction to accept the legacy devised to it by Philippe Ricord for the foundation of a prize to be awarded every two years to the author of the best work on venereal disease which appears in the intervening period.

The Death of a Patient under treatment with parataloid, is reported from Glasgow, and another from Russia.

New York Physicians' Mutual Aid Association.—The twenty-second annual report of the New York Physicians' Mutual Aid Association, just issued, shows a very prosperous condition of the society. The membership has largely increased during the year. Eight hundred and twenty-five dollars is now paid upon the death of a member. We renew our commendation of this society to the members of the profession throughout the State.

Dr. Pierson Rector, of Jersey City, died on January 22d, of blood-poisoning contracted while attending an obstetrical case. Dr. Rector was born in 1838. He attended the Albany Medical College. At the outbreak of the war he became Surgeon of the One hundred and fifty-second New York Volunteers, and was made Assistant Surgeon-General, serving under Meade, Sherman, and Grant. He continued in the army till 1878, and then moved to Jersey City, where he rapidly acquired a large practice.

The United States Marine Hospital Service.—Surgeon-General Hamilton has sent in his report for the year ending June 30, 1890. It shows that in the 19 United States marine hospitals and in the 120 sub-stations at which hospital relief is furnished, 50,671 sailors were cared for in the year, of whom 14,587 were treated in the hospitals proper, and 36,084 in the dispensaries. The nationalities of these patients were as follows: 6,916 Americans, 1,655 Norwegians and Swedes, 1,349 Irishmen, 775 Germans, 552 Canadians, and the rest from all parts of the globe. Dr. Hamilton recommends a new hospital at Sitka, Alaska, and reports the temporary establishment of a floating hospital in Chesapeake Bay for the relief of oyster dredgers. During the year 2,976 pilots were examined for color blindness, and 41 were found to be suffering from that defect. Of 1,061 keepers and surfmen in the Life-saving Service who were examined for physical ability in the performance of their arduous duties, 72 were found to be below the mark. As the Government took charge of immigrant inspection at the port of New York last year, the Hospital Service was charged with the medical examinations, and a temporary hospital was fitted up at the Barge Office; but a large hospital and insane asylum for the immigrant service is being established upon Ellis Island by the Treasury Department. The report contains a special description of the origin, cause, and termination of the "grippe" epidemic, and calls attention to the unhealthy condition of the ports of Havana and Rio Janeiro. Dr. Hamilton would like the United States to give funds to have them improved sanitarily, as the prevalence of yellow fever there is a constant menace to the health of this country.

The Northwest Texas Medical Association will meet in Abilene, Tex., on the first Tuesday in February.

The Gentle Medical Man.— Nothing can be said of the physician, and especially of the surgeon, more to his honor than to say he was gentle. When this gentleness is real, and is manifested toward all—dispensary patients and private alike—it is based on a sympathy which does the wisest credit.—*North American Practitioner.*

The First Case Cured by Koch's Parataloid.—It is stated that one of the patients who suffered from phthisis and was treated at Bellevue Hospital by the Koch injections has been discharged cured, and is now exhibiting himself in a Bowery Museum as "The first American cured by Koch's Lymph."

Effect of Parataloid on the Sputum of Phthisical Patients at Davos.—Since November 17th, 400 patients have been treated by the Koch method at Davos. Dr. J. Amann has made bacteriological investigations of the sputum of 288. He finds that the injections increase the amount of sputum and the number of bacilli; their form is also somewhat changed, and they take up the stains more readily. There is also an increase in the number of elastic fibres of the sputum.

Dr. Koch's Relations to the German Government.—The following very clear account of the relations of Koch to the government, and of his first experimental work with the parataloid, is given in the *British Medical Journal*. "Dr. Koch has been for many years the director of the Hygienic Laboratory in Berlin. This laboratory is a government institution, maintained by the Educational Department of the German Government, and Dr. Koch, as its director, has been an officer of that department. All the earlier experiments for the discovery of the now famous lymph were conducted in Dr. Koch's own laboratory in the Hygienic Institute, and there the observations upon guinea-pigs and other animals which emboldened Dr. Koch to proceed to inoculate human beings, were made. The laboratory, however, presented no facilities for making these investigations upon human beings, and Dr. Koch holds no official position with regard to any of the Berlin hospitals. He therefore found himself in a practical dilemma, inasmuch as if he were to make his experiments in a public hospital it was feared that the premature and eager discussion of incomplete observations and immature results might easily tend to interfere materially with the investigations and to produce evil results. Dr. Koch consequently hired a private house at his own expense, and obtained the assistance of two gentlemen with whom he had private acquaintance—Dr. Libbertz, an old schoolfellow, and Dr. Pfuhl, his own son-in-law. The lymph was prepared in considerable quantities in this private house by these two gentlemen under Dr. Koch's supervision, and the earliest injections in man were made in the private hospitals of Drs. Cornet and Levy. It soon became evident, however, that the interest, both among the general public and in the medical profession was too keen to permit of the continuance of the investigation upon these lines: and Dr. Koch, acting on the advice, or perhaps it might be correct to say upon the instructions, of Herr von Gossler, the Minister of Education, published the now famous preliminary paper, and distributed the lymph to certain of the hospitals in Berlin. Meanwhile, the manufacture of the lymph was carried on in the private house by Dr. Koch and his two personal private assistants. Recently this arrangement has ceased; the house in which the lymph is manufactured has been taken over by the Education Department of the German Government, and Drs. Pfuhl and Libbertz have become officers of that department. The Koch Institute, which the German Government are now erecting, will consist of two parts—a laboratory and a clinical department containing one hundred and fifty beds. The clinical department will probably be under the direction of Professor Brieger. The observation and treatment of the patients received into it, it is hoped, will afford in the future opportunities for Dr. Koch to prosecute his studies with regard not only to tuberculous diseases, but to tetanus, diphtheria, and typhoid fever. In this way the inconvenience which has arisen from his having no clinical wards of his own will be avoided. In the laboratory bacteriological investigations will be carried on, and at the earliest possible date the laboratory for the preparation of the anti-tuberculous liquid will be transferred to this department of the Koch Institute. The director of this bacteriological department has not yet been appointed, but the whole institute will be under the general direction of Dr. Koch, who will remain an officer of the Education Department."

Delayed Reaction from Lymph.—Dr. Karl von Ruck, B.S., M.D., of Asheville, N. C., writes: "In my experience with Professor Koch's method I have a unique experience to record, which is no doubt of interest to others who are carrying out the work, and the knowledge of its possibility may avert serious consequences.

"In a case of early stage of pulmonary tuberculosis, without expectoration, the remedy was applied to confirm the diagnosis, for the first time on January 9th, no reaction occurring to 0.001 gm. On the 11th, she received 0.0015 gm., again without reaction, either general or local; on the 13th I injected 0.002 gm., and although observations of temperature, etc., were made every two hours, no reaction had occurred on the morning of the 14th, or twenty-four hours after the last injection was made. The patient was now very anxious to avoid further delay, and pleaded for another injection and increase of dose, which, in view that there is not a single case on record in which reaction occurred later, might have been granted. I fortunately decided to wait until the next day, and contrary to expectation the patient reacted at 4 P.M., or thirty hours after the last injection, with a severe chill, rapid rise of temperature to 102° F., nausea, pain in abdomen, a rapid weak pulse, headache, and general depression, and profuse perspiration, this condition lasting twenty-four hours, when the normal state was again reached. To-day a similar but not quite as severe reaction occurred after injection of only 0.0015 gm., a dose to which previously no reaction occurred at all, and this time after twelve hours only.

"The fact that the reaction may be delayed for so long a time, and then again occur in the same patient within the usual limit, should make it an absolute rule never to repeat the treatment short of forty-eight hours, and I have no doubt, had I acceded to the wishes of my patient, I should have had good reason to regret the haste."

The American Electro-Therapeutic Association held its first meeting for organization at the New York Academy of Medicine, on Thursday, January 22d. The following officers were elected: *President*—Dr. G. Belton Massey, of Philadelphia; *Vice-Presidents*—Dr. W. J. Morton, of New York, and Dr. A. H. Goelet, of New York; *Secretary*—Dr. W. H. Walling, of Philadelphia; *Treasurer*—Dr. George H. Rohe, of Baltimore.

Brown-Séquard's Fluid vs. Koch's Lymph.—Dr. D. Uspenski, in a lecture recently delivered before the Russian Society of Public Hygiene (*Deutsche Medizinal-Zeitung*, December 29, 1890), gave an account of some clinical experiments which he had made with Brown-Séquard's "emulsion" in the treatment of tuberculosis. He had tried this preparation in eighteen patients in different stages of the disease. Two of them had been quite given up. He consider sthat Brown-Séquard's fluid has a markedly strengthening effect, and is beneficial in all cases of phthisis without exception, whether the patients have any additional treatment or not, and whether they live under favorable conditions or the reverse. The tubercle bacilli do not disappear entirely, even in the most successful cases, but diminish in number in proportion to the extent to which the diseased process recedes. Uspenski says the remedy does not kill the bacilli, but weakens their pathogenic power.

Unconscious Parturition.—Abnormally easy parturition sometimes occurs under circumstances which result in the death of the child. Such cases, therefore, may have a medico-legal importance. Dr. Brunon has recently reported such a case and cited several others. A married woman, aged twenty-two, had a troublesome cough one day shortly before term. The coughing was accompanied with lumbar pains, which increased. At eleven o'clock in the evening the patient tried to pass a motion. She sat over one hour in the closet, believing that her pains signified painful defecation. Then she went to bed. At half-past one o'clock she woke up feeling a desire to pass a motion, with lumbar pains such as she had felt before when constipated. As she rose to go to stool a smart lumbar pain occurred, and she felt something between her thighs. On handling it she found, much to her surprise, that it was the head of her first-born. She declared to Dr. Brunon that the pains were entirely lumbar, she had no colicky sensations, and none of the expulsive pains, usually so severe, especially in primiparæ. The desire to defecate was strong, and she stated that the child might have been born into the pan of the closet without her recognizing the truth of her condition till the moment of its delivery. The patient was an intelligent, well-educated woman, free from any neurosis. This cases proves that in the case of an inexperienced person an infant might be expelled into the water in the pan of a closet without any intention of infanticide on the part of the mother.

Public Surgical Operations.—We are a little in doubt whether the following, published in an Omaha daily paper, is to be taken seriously: "Last evening the large attendance at the People's Theatre, in addition to the usual entertainment given by the great German Polyclinic doctors, were witnesses of several difficult surgical operations that were undertaken and most successfully accomplished in full view of the packed audience, including a number of Omaha's leading physicians. They were pronounced by those who know to have been most skilfully and scientifically handled. The first case was a large tumor removed from the right cheek of William Villiers, of the Millard Hotel billiard-room. One of the doctors of this staff conducted this operation, and it was eminently successful; and the result will be, William Villiers before long will be all right. Another operation requiring great skill was relieving the little eight-year-old son of F. M. Kiger of strabismus (or cross-eyes). Cases of this kind require the greatest of care and experience, and were most satisfactory evidence of what these doctors can do. These entertainments are most instructive and pleasing. Nothing is done to which the most fastidious can take exception, ladies being always especially pleased. These notable physicians can be consulted at their office in the Barker Building. Operations and entertainment each evening at 8 P.M., at the People's Theatre. Admission free to all."

Homœopathy in Russia.—Homœopathy is said to be spreading in Russia, especially in the upper social strata. Societies for the propagation of the Hahnemannian doctrines have recently been established at Tschernigow, Odessa, and Warsaw. As has been noticed in other countries, the clergy are conspicuous among its supporters; in Russia the military mind seems also to have an elective affinity for globules and infinitesimal dilutions. Thus at Tschernigow one of the founders of the new society is the bishop. At Odessa, among those who have signed the draft statutes of the society, are the Archbishop of Cherson, Generals Count Rostowzew, Roop, Teplow, and Strandmann, and the mayor of the city.

The Technique of Magnetic Healing.—A representative of the *Times and Register* recently visited a somewhat notorious "magnetic healer," and in the guise of a patient obtained some interesting facts regarding "magnetic healing." The reporter asked if his method was like that of the Christian scientists. "Yes," was the answer, "the results are all obtained in the same way; magnetic healing, hypnotism, Christian science, and electricity are all the same thing."

"Do you hypnotize your patients?"

"No; I don't think you could call it hypnotism, although it amounts to the same thing. I don't put them to sleep, but heal them instantly."

"What method do you employ?"

"If the patient has rheumatism, I simply place my hand on the affected limb and ask if he feels pain. 'Yes,' is replied; then I do so—" and here the "doctor" frantically waved his hand in front of our representative's face—"and say, 'Throw away your crutches; the pain's gone; you're well.' And sure enough he is. Then I tell him to jump about, and stamp his feet, or otherwise use the limb violently, but no pain can be induced."

"To be sure," he added, "this condition may last only a few weeks; but two or three such treatments will produce a permanent cure."

"How do you account for such cures?"

"I don't account for them; I can't explain them; I only know I can do it. But I do not always use it, as few can afford to pay for it; and then it is very weakening, and exhausts me greatly."

"What are your charges?"

"Never less than $10, and up to $100."

"You give stage performances, do you not?"

"Yes; and have greater success in treating people on the stage than in private practice."

Reviews and Notices of Books.

Wood's Medical and Surgical Monographs. Volume VII., No. 1. Contents: Stricture of the Rectum, by Charles B. Kelsey, M.D.; Influence of Heredity on Alcoholism, by Paul Sollier; Rabies, by Louis Pasteur; Colotomy, Lumbar and Iliac, with Special Reference to Choice of Operation, by Thomas Bryant, F.R.C.S.; Massage of the Abdomen, by Rubens Hirschberg, M.D. July, 1890. New York: William Wood & Co.

"Stricture of the Rectum." A Study of Ninety-six Cases. The means for treatment advised are: 1, Dilatation; 2, Incision; 3, Partial Destruction, including Electrolysis and Raclage; 4, Excision; 5, Colotomy; 6, General Treatment.

By dilatation is meant gradual stretching, not forcible divulsion. Many will here read for the first time that nothing is productive of more evil than forcing a bougie through a stricture when the instrument is too large to be passed without pain and violence, and that no good is ever accomplished in that way. A size should be selected which will pass through the stricture without force, and which may be left in place several hours without causing uneasiness. Incision must always be followed by stretching with the bougie. The results aimed at in partial destruction, electrolysis, and raclage can all be better gained by linear proctotomy. As to excision—extirpation of the rectum—the class of cases to which this operation is applicable is day by day increasing; it is no longer limited to stricture due to malignant disease.

"The Influence of Heredity on Alcoholism." Dr. Sollier has based his discussion upon the history recorded, as carefully as possible, of three hundred and fifty families, one of the members of which was at the time, or had been, at Bicêtre, in the wards of the Epileptic and Idiotic Children. The author has peculiar views concerning the mutual relations of dipsomania and alcoholism by heredity. According to him there is between these two pathological conditions merely a difference of intensity in the impulse, a difference of excitation which effects a varying reaction that permits the one to eliminate the ingested alcohol and leads the other to intoxicate himself. Thus, for each of the morbid conditions a particular course results, and the two become more and more divergent. The work is well co-ordinated, easily followed in its developments, careful in its details, and confined to the subject.

"Rabies." The evidence that the lower animals can be perfectly protected from rabies by proper inoculations is considered absolute by Pasteur. The experiments of others are not altogether so satisfactory, but they show that some immunity is unquestionably conferred, and in general confirm the truth of the principle. It may be yet asserted that its application to man is imperfectly developed, and that it still remains to be shown that antirabic inoculations should be widely adopted. As to this a difference of opinion is allowable. To many who have only read in the lay press of M. Pasteur's work this short paper will be very interesting.

"Colotomy, Lumbar and Iliac, with Special Reference to Choice of Operation." The work of Mr. Herbert Allingham and of Mr. Cripps is given a careful consideration, and the author's one hundred and seventy cases analyzed. In conclusion Mr. Bryant says: "It is therefore clear that iliac colotomy is not yet proved to be superior to the lumbar operation. In doubtful cases, in which an exploratory incision is required for diagnostic purposes, it may be useful, but such cases are very few; in all others, lumbar colotomy has advantages which stamp it as the better measure."

"Massage of the Abdomen." In the works of Nordstrom, Schreiber, and Reibmayr-Petit, otherwise very complete, massage of the stomach is not even mentioned. It is to this part of massage of the abdomen that especial attention is given in the paper before us. The worth of the author's views may be gauged by the knowledge that he holds that massage of all abdominal organs should be done by the physician himself.

Wood's Medical and Surgical Monographs. Volume VII., No. 3. Contents: Insomnia and its Therapeutics, by A. W. Macfarlane, M.D.; and the Index to Volume VII. September, 1890. New York: William Wood & Co.

Insomnia is one of those little things which many physicians are wont to forget in health, and pass over without consideration in the study of disease; too many give it no thought unless relief be demanded by the patient, and then take refuge in one or two of the half dozen hypnotic drugs, seeking only a temporary relief. The knowledge of how to treat successfully a single symptom, like insomnia, is often a better index to the successful practitioner than profound disquisitions upon the germ-theory. And the patient often appreciates the relief of an annoying symptom more than the cure of a serious disease or the conservation of life. It is to the consideration of this condition—insomnia—then, that Dr. Macfarlane devotes this entire number of Volume VII., some three hundred octavo pages. The opening chapter is devoted to the physiology of sleep; the second to general remarks on insomnia. The remaining chapters take up insomnia and its treatment, due to the following causes: Overwork, shock, depressing emotions, neurasthenia, hysteria, hypochondriasis, insanity, myxœdema, spasmodic and paroxysmal neuroses, affections of the brain and its membranes, affections of the spinal cord and nerves, alcohol, morphine, chloral, cocaine, tea, coffee, tobacco, gastric and intestinal dyspepsia, constipation, intestinal worms, disorders of the liver, jaundice, gout, affections of the circulatory system, affections of the respiratory system, febrile and general diseases, affections of the urinary system, and insomnia peculiar to women. In the concluding chapter baths and electricity receive consideration.

Essentials of Anatomy and Manual of Practical Dissection, together with the Anatomy of the Viscera. Prepared especially for Students of Medicine. By Charles B. Nancrede, M.D. Third Edition, revised and enlarged. Based on the last edition of "Gray's Anatomy." Thirty full-page Lithographic Plates, in colors, and 180 Wood-cuts. 8vo, pp. 388. Philadelphia: W. B. Saunders. 1890.

While this book cannot replace the larger anatomical works, sufficient descriptive matter has been introduced to enable the student to refresh his memory of the more numerous facts learned in the lecture- and dissecting-room, or from his "Gray," differing in this respect from most of the works of this class, which are little more than a list of names.

Ointments and Oleates, Especially for Diseases of the Skin. By John V. Shoemaker, A.M., M.D. Second Edition, revised and enlarged. 8vo, pp. 298. Philadelphia and London: F. A. Davis. 1890.

This volume is No. 6 in the Physicians' and Students' Ready Reference Series. It is a *résumé* of the various papers written by Dr. Shoemaker on the subject of the oleates and their uses, and a very complete survey of the manner in which, and purposes for which, fatty substances are applied to the human body. In addition to our officinal ointments the author has described those which are commonly used in this country—those substances which are used extemporaneously—and the officinal British ointments. The officinal lists of France, Germany, and Austria are also given, while those familiar in the practice of Italy, Spain, and the Spanish colonies have been compiled from all available sources. The reader may thus obtain a conspectus of the whole subject of inunction as it exists to-day in the civilized world.

Eighth Annual Report of the State Board of Health of the State of New Hampshire, for the Eighteen Months ending October 31, 1890. Manchester: John B. Clarke. 1889.

It is generally difficult to understand why State Boards of Health print volumes of annual reports. This volume now before us has a very good reason for its being, inasmuch as it contains at least one paper of unusual value, to wit, "Practical Sanitary and Economic Cooking," by Mrs. Mary Hinman Abel, being the Lomb Prize Essay for 1888, under the inscription, "The Five Food Principles, Illustrated by Practical Recipes." Scarcely too much can be said in favor of this essay, which, as the Secretary of the American Public Health Association tells us, with truth, is unequalled, and should be put in the hands of every woman interested in household economy. We have read many books on this subject, and we know of none which contains so much valuable information, though in general they cover many more printed pages. To the beginner in housekeeping the work is invaluable, covering in two hours' careful reading all the principles of cookery, so arranged as to be easily found, and so simple and lucid in statement as to be quickly mastered and easily remembered. That this essay may be placed in the hands of every family in the country is the earnest desire of the gentleman giving the prize, as well as that of the Association; therefore a price barely covering the cost has been placed upon this volume.

The Latin Grammar of Pharmacy and Medicine. By D. H. Robinson, Ph.D. Philadelphia: P. Blakiston, Son & Co. 1890.

All teachers in schools of pharmacy and medicine have long felt that a knowledge of Latin was essential to a thorough comprehension of the language peculiar to their work. The student, however, who looks mainly to the practical side of the subject—seeing but a remote connection between the ordinary Latin text-book and the special knowledge he requires—throws aside any systematic study of this important language, deeming it a waste of valuable time. In order that the student, while learning Latin, might learn the names of drugs and many of the formulæ for preparing medicines, and thus make the study of the language practical and bearing directly upon his life-work, this book was written. It follows to some extent the plan of Collar & Daniel's "Beginner's Latin Book," and will be appreciated by all teachers and all students who have not had the advantage of a classical education.

Saunders's Question-Compends, Nos. 8 and 9. Essentials of Practice of Medicine. By Henry Morris, M.D. With an Appendix, on the Examination of Urine, by Lawrence Wolff, M.D. Philadelphia: W. B. Saunders. 1890.

This series of question-compends is so well known that it is necessary to say very little about them. Intended for the use of the undergraduate and the young practitioner they supply ready hints to recall knowledge obtained from more voluminous sources. It may, of course, be properly questioned whether knowledge obtained in this way is ever desirable; but so long as students are judged by superficial examinations there will be a demand and a use for works of this kind. This present double-number volume is one of the very best of the series, and shows a painstaking thoughtfulness that may well be imitated by more pretentious volumes.

Saunders's Question-Compends, No. 15. Essentials of the Diseases of Children. By William M. Powell, M.D. Philadelphia: W. B. Saunders. 1890.

The subject is discussed mainly from the symptomatic and therapeutic stand points, the questions of diet, general hygiene, and nursing being less fully considered. In a work of this kind, intended chiefly as an aid to the undergraduate and for use in the quiz, only the briefest enumeration of the necessary facts can be expected, but we may reasonably expect the nicest accuracy. This we do not always find, to wit: Torticollis is defined as "a rheumatic pain involving the muscles of the neck," and the diagnostic symptom, "pain on turning the head." This may be the symptom of rheumatism of the neck, whatever that may be, but it certainly is not the diagnostic symptom of torticollis; and further, it is so misleading that cervical spinal caries would be very sure to be mistaken for torticollis and treated with poultices and saline laxatives.

Epilepsy: its Pathology and Treatment. By Hobart Amory Hare, M.D., B.Sc. 8vo, pp. 228. Philadelphia and London: F. A. Davis. 1890.

This is volume No. 7 in the Physicians' and Students' Ready Reference Series. It is the essay to which was awarded a prize of four thousand francs by the Académie Royale de Médecine de Belgique, December 31, 1889. The author believes that it is fairly representative of the views held by the best minds of the profession, and has endeavored to separate the good material in literature from a vast mass of superstition and nonsense which persons even in our own generation have contributed.

Leçons sur les Maladies du Larynx. Par le Dr. E. J. Moure. Paris, 1890.

Among the French writers on laryngology there is perhaps no one whose writings are better known than E. J. Moure, of Bordeaux. This author has recently followed his small work on "Maladies des Fosses Nasales" by a volume on "Maladies du Larynx." In this is much matter not always found in such treatises, as, for instance, a good account of the laryngeal complications of the eruptive diseases, a timely chapter on "La Grippe," and a comprehensive essay on abscess of the larynx. We believe the division between simple primary abscess of the connective tissue and abscess secondary to perichondritis ought to be more strongly drawn. The author, believing that it is the receptivity of the patient that ought to be modified, rather than to sacrifice the patient in order to kill the bacillus, leans to the older treatment of laryngeal tuberculosis. Hennig's and Krause's methods of curetting, followed by the application of lactic acid, is condemned. Rather, as local treatment, is the inhalation of soothing and astringent medicaments advised, such as balsam of Peru, carbolic acid, eucalyptus, creasote, and emulsions of sulforicinate of soda with naphthol and salol. Cocaine and iodoform in solution are used as local anæsthetics.

Intubation in chronic syphilitic stenosis is barely alluded to; and no mention is made of its use in acute cases of laryngeal stenosis. This is a grave omission, the operation having been proven by recent and ample experience to be of unquestionable value in this class of cases. Lupus and scrofula of the larynx are described as the same morbid process—"a form of tubercular laryngitis with few bacilli"—and as a natural corollary, the treatment recommended is the same. In these cases, in addition to remedies directed to the general condition, caustics and curetting, followed by the application of lactic acid, find proper employment, according to this author.

On the subject of laryngeal paralyses—especially those causing narrowing of the glottic orifice—the recent work of Donaldson and Hooper in America, Semon and Horsley in England, and Tissier in Paris is reviewed. Dr. Moure places himself among the opponents of Semons's theory that the superficial nerve-fibres of the recurrent laryngeal supply the crico-arytenoid posterior; and therefore, pressure on this nerve is first indicated by paralysis of those fibres, and consequent abolition of function of the abductor muscle of the cord. There is no reason to suppose that the vagus or the recurrent branch differs from other nerves physiologically; and the theory that neuritis, or compression of the nerve, produces at first

adduction (contracture—*sic*) of the cord by stimulation, and later by paralysis, is the most rational explanation of these phenomena.

Spasms of the muscles of the larynx are classified etiologically—making a good working division—1, Functional spasm; 2, spasm by direct irritation; 3, spasm of peripheral origin; 4, spasm of central origin; 5, reflex spasm; 6, spasm related to a general affection (*i.e.*), chorea of the larynx and "nervous cough."

Pasteur and Rabies. By Thomas M. Dolan, M D. Pp. 83. London: George Bell & Sons. 1890.

In this small work is given the "other side" of the rabies question. Pasteur's methods and statistics are mercilessly criticised. The records of the Paris hospitals have been very carefully searched to verify the position taken. Likewise the position taken by the English Hydrophobic Commission is assailed. It is extremely difficult to decide in such a case as this which party is right. The evidence is conflicting at every report. The Medical Record's disbelief in the entirety of Pasteur's claims has been previously expressed. Dr. Dolan's views must, however, be carefully examined by anyone desiring to hear both sides. If his data are right (which we doubt not), his conclusions leave the Pasteur doctrinaires without ground on which to stand.

Bacteriological Technology. By Dr. C. J. Salomon, Sr. 8vo, pp. 162. New York: William Wood & Co. 1890.

This work is a translation from the Danish, by William Trelease, and is now, in its second and enlarged edition, well illustrated. The author's preface declares his intention to be the outlining of bacteriological courses for physicians who wish to take up the subject at home without an instructor. No exhaustive presentation of the subject is therefore attempted. Only simple and easily managed methods and apparatus are described, and an equipment not too expensive for the average physician is suggested. No previous work covers exactly this ground, and therefore the book needs no apology for its appearance. The name of the author is a voucher for its accuracy. The translator's work is creditable.

The Medical Student's Manual of Chemistry. By R. A. Witthaus, M.D., Professor of Chemistry in the University of the City of New York, etc. Third Edition. Pp. 528. New York: William Wood & Co. 1890.

The principal change from previous editions is in that portion treating of the chemistry of carbon compounds, which has been in great part rewritten in accordance with our latest knowledge. Being written for medical students, it departs at times from the province of pure chemistry and discusses (as all such works should) the relations of the subject-matter taught to practical medicine. It contains everything in the line of chemical instruction that a medical student needs.

Familiar Forms of Nervous Disease. By M. Allen Starr, M.D, Ph.D. With Illustrations, Diagrams, and Charts. Pp. 339. New York: William Wood & Co. 1890.

The first eleven chapters of the present work are devoted to an exposition of the functions of the brain and cord, a description of the important points in anatomy, and a discussion of the methods of diagnosticating focal lesions in various parts of the central nervous system. These chapters contain an excellent summary of our present knowledge of these subjects. The descriptions are clear, direct, and accurate, and they cannot fail to be helpful to the practitioner. They are illustrated with cases.

The more strictly clinical part of the work consists of chapters upon "Locomotor Ataxia," by Dr. W. W. Skinner; on "Paralysis Agitans," by Dr. Frederick Peterson; on "Chorea," by Dr. Wallia Vought. There are chapters by the author on "The Paralysis of Infancy," "Multiple Neuritis," "Epilepsy," "Neuralgia." "Neurasthenia," and an excellent and practical chapter on "Insanity," by Dr. Peterson. These clinical chapters are perhaps of less real value than the first part of the book, but all contain matters that will be found suggestive and useful, and are especially interesting as illustrating American types of disease. It is the part of the reviewer to find some fault, and we are inclined to think that Dr. Starr takes a backward step in referring all idiopathic epilepsies without aura to the medulla, and in considering as cortical only the Jacksonian type and those beginning with an aura.

In the first part of the book is a diagram of the cerebral convolutions, from Eberstaller. While the fissuring is correct, the indicated position of the anterior occipital fissure (Wernicke's) is wrong. This is Eberstaller's fault, however. Such criticisms as the above will not, we are sure, disturb the impression we feel and desire to convey that Dr. Starr's book is in every way creditable to the author, and one that cannot fail to be useful to the student of nervous diseases.

The typographical work is unusually well done, and the cuts are excellent.

Wood's Medical and Surgical Monographs. Published Monthly. October, 1890. Contents: Suppuration and Septic Diseases, by W. Watson Cheyne, M.B.; Pharmacopœia for Diseases of the Skin, by James Startin; The Nasal Neuroses, by Granville McDonald, M.D.; Artificial Respiration—the Theory and Practise; by Benjamin W. Richardson, M.D; The New born Infant, its Physiology, Hygiene, and Nourishment, by Dr. A. Auvard; The Urine in Neurotic Diseases, by Dr. Alexander Peyer. New York: William Wood & Co. 1890.

"Suppuration and Septic Diseases." Of late years a certain antagonism has arisen between bacteriologists working in laboratories and clinical observers who do not possess a practical knowledge of bacteriology. The bacteriologist, directing his attention mainly to the bacteria, has tended unduly to overestimate the importance of these organisms; while the clinician, looking at the matter from the side of the body, has realized that an infective disease is a complex process, and has too often underestimated the importance of the causal organisms. The writer is one who has studied the subject from both points of view, though more from the clinical than from the bacteriological side, and has directed his efforts to attempts to reconcile the apparently conflicting evidence.

"Pharmacopœia for Diseases of the Skin." The paper is made up of the formulæ used in the London Skin Hospital, and a condensed classification of skin diseases. Subjoined notes render the arrangement readily understood.

"The Nasal Neuroses." Like most reflex neuroses, those of the nose are an interesting study in just the proportion that they are unsatisfactory of treatment. This short paper will be found well worth the reading.

"Artificial Respiration." This subject is one which, for the last hundred and twenty years, has, from time to time, called forth the study of the experimentalist, and after him the practitioner, but nothing has been sufficiently carried out in a strictly scientific and uniform manner. In this paper the author attempts to point out how to arrive at some uniformity of action, both in principle and procedure.

"The New born Infant." The writer holds that the hygiene of the child begins with conception. At this point he takes up the subject and carries it through the commonest diseases from which the new-born may suffer.

"The Urine in Neurotic Diseases." The effects of nervous diseases upon the urine are becoming every day better understood; and this short paper formulates in a very clear manner many things which heretofore have been but imperfectly remembered.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 15, 1891.

ALFRED J. LOOMIS, M.D., PRESIDENT, IN THE CHAIR.

Cervical Adenitis in Children.—The discussion on this subject was in charge of the section on pediatrics, and was opened with a paper by DR. A. JACOBI, who treated of the etiology, symptomatology, and diagnosis. Dr. Jacobi prefaced his remarks on these three headings with a reference to the anatomy of the lymphatic system, particularly of the cervical, and referred his listeners for a succinct account of this part of the subject to the second volume of Keating's Cyclopædia. Lymph glands, he remarked, was an inappropriate term, since they did not secrete; they were simply receptacles. Nor could they properly be called bodies, but for convenience these terms were still retained. The large number of cells which formed the bulk of the lymph glands, and their near approach to the embryonic state, accounted for the ease with which tumefactions were brought about. Foreign bodies or chemical changes within the lymph bodies caused irritation and disease.

Etiology.—The etiology of glandular tumefaction, both cervical and general, on the basis of hyperæmia or inflammation, was mentioned under two heads: 1, General infection might act through the blood, as in universal putrid and septic infection, in anthrax, leprosy, leucocythæmia and pseudo-leucocythæmia, under the influence of Koch's lymph, in syphilis, also in enteric fever. 2, But the large majority of cases of adenitis, both acute and chronic, owed their existence to a local influence. They were produced by pathological or chemical changes in the circulating lymph which resulted in irritation of the lymph glands. That result was mostly an acute adenitis, which might undergo resolution or become chronic.

There might be a predisposing tendency, either congenital or acquired, yet most cases of adenitis were of local origin, and that local origin should be traced in every case, when possible. It was more difficult in the old or chronic cases.

The local origin might be a lesion of any kind. The best protection against cervical or other forms of adenitis was normal health and absence of lesions of the integument and mucous membrane. Among the local causes might be mentioned trauma, erysipelas, insect bites, pediculi, mastoid disease, aural catarrh, oral disease, so-called fever-blister, herpes zoster. The nose was a frequent source of adenitis; every ailment interfering with the healthy action of the mucous membrane, from the simplest to the severest catarrh, from lesions produced by foreign bodies to the septic influence of nasal diphtheria, might give rise to it. Not a small number of cases of so-called scrofulous glands of the neck for which the children had been punished with cod-liver oil, had in other hands been cured by simple treatment directed to the nose. Adenitis, connected with intestinal parasites, might be accounted for by the child using the finger to relieve reflex irritation set up in the mucous membranes at the entrance to the air passages.

Septic adenitis set up by nasal diphtheria need no longer be considered so hopeless a disease since we now recognize the benefit of treating the local lesions. If the glands swelled under the influence of septic infection, in like manner should they diminish under the influence of cleanliness and disinfection. In mentioning cracked lips, stomatitis, injured tongue, etc., as sources of adenitis, the author repeated and emphasized the statement that there was no protection better than intact integuments. The cracked tongue of the typhoid-fever patient formed the inlet for all kinds of microbes, and these, he thought, were the cause of more deaths than the original infection.

In some remarks on the diagnosis, the author said it was not easy always to tell whether pus was present or not, especially if there were separate multiple abscesses. Where they ran together and formed a large abscess, presence or absence of fluctuation was likely to depend on the thickness or rigidity of the capsule. Sometimes there was a small circumscribed soft spot which could be detected by steadying the glands between the fingers of one hand and palpating with one of the other. When the neighboring organs became implicated, the skin red and sensitive, the diagnosis became easy, whereas the sense of fluctuation might be deceiving. Semi fluctuation was characteristic of sarcoma of almost every region. The presence or absence of the same kind of swellings in other parts of the body would aid in the diagnosis of cervical adenitis due to certain affections, as Hodgkin's disease, pseudo-leucocythæmia, etc. To distinguish glandular abscesses in the cervical region from pus having a different and a deeper origin was also sometimes difficult and might test the observer's experience and dexterity.

The Medical Treatment.—DR. WILLIAM H. THOMSON prefaced his remarks on this subject by saying that he agreed with Dr. Jacobi that a cervical adenitis was usually the result of some local infection; in other words, of some infective material brought to the gland by its lymph channel from a local lesion. Besides this, however, we might add another factor, namely, the greater or less amount of resisting power. He believed this had as much to do with the adenitis as the specific infection itself. Entertaining this view, he had for years considered the question why children should have adenitis nine times to adults once. What was there in the constitution of children which predisposed them to this form of infection, especially as it affected the lymphatics of the neck? There must be some physiological basis for it, and he believed it was referable peculiarly to the great activity of the nervous system at this age. When we reflected, he said, that the brain grew nearly to its full weight for life between the second and seventh years, an example was afforded of more rapid growth and more actual increase in bulk in a given period than in any other tissue or organ of the body excepting the pregnant uterus. During this period, too, the brain went through greater functional activity than it would ever do again. It had to acquire language, acquire impressions of the external world, form ideas thereon, etc. He said that if the brain of the adult could learn in one year what the brain of the child learned in one month of entirely new acquisitions, and learn them as well and as permanently, man would become a prodigy in a few years. This rapid growth of this highly endowed and vascular organ of the body drew upon the blood to a greater degree than was done by any organ at a subsequent period. This great drain upon the system left the other organs in relatively a condition of poverty. Whatever might happen, there was one tissue in the body which would not cease its demands upon nutrition, namely, nervous tissue. It was the only tissue which did not lose bulk in starvation. The relatively poorer tissues showed the first signs of starvation. The first indication of the starving process would be noticed in the cornea of the eye, then in the hair, in the skin, etc. Scrofulous children had short, stubby hair, wanting smoothness and gloss; the skin became harsh and dry. Ultimately he traced these conditions, signs of failing nutrition, to the excessive demands of the brain upon the nutritive supply. With a harsh skin there went such conditions as phlyctenular conjunctivitis, otorrhœa, chronic naso-pharyngeal catarrh, enlarged tonsils, eruptions upon the scalp, conditions which, as Dr. Jacobi had said, favored adenitis. Therefore, in the treatment of the disease he considered the kind of food which would supply the materials demanded by the nervous system. For that reason he believed the greatest prophylactic in adenitis was cod-liver oil. That it supplied food called for by the system at this age was evi-

dent from the fact that children cried for it while adults found it repulsive. No other agent produced equal results in increasing the red blood-corpuscles. He had very little confidence in the medicinal action of the iodides in very young children, although after the twelfth year iodine itself was at times of benefit. The physician in charge of an orphanage once told him he had a large number of cases of scrofulous abscesses for which he had tried every remedy, including iodides, unsuccessfully. Dr. Thomson told him to try Lugoll's solution in one- or two-drop doses, or tincture of iodine. He did, and reported favorably.

Chloride of Calcium.—There was one other agent which he had had occasion to use in a way to put it to a severe test, in consultation cases where ordinary means had failed. He referred to chloride of calcium. He gave the United States officinal solution, half a teaspoonful, increased to a teaspoonful, for a child, diluted with equal parts of syrup of ginger, taken in water immediately after meals.

The Surgical Treatment.—Dr. A. G. Gerster opened the discussion on this phase of the subject. He emphasized the point that modern surgeons, in treating adenitis, did not rely solely upon the knife; they treated the general condition of the patient, but since that phase of the subject had already been discussed, he would say little upon it. Speaking, then, of the local surgical treatment, he said that the first question in a case of intumescent glands was, had we to deal with an acute or a chronic complaint? Acute glandular affections had to be dealt with generally in a different manner from the chronic. If, after giving attention to the etiological indication we did not succeed in causing the intumescence to disappear, particularly if there were fever, we should suspect pus in the centre of the gland. If the glandular intumescence were steadily increasing, and the signs pointed to hidden pus, the tension should be relieved by incision. The popular method was to apply poultices. He did not object to it as a tentative measure, but it should not be persisted in long. If the glandular disease were deep seated and the physician feared he might injure important vessels in making his incision, let him lay the knife aside after passing through skin and superficial structures. If doubt were felt as to the direction of the pus, insert the hypodermic needle. Finding pus, before withdrawing the needle introduce alongside of it a grooved director, then withdraw the needle and along the grooved director introduce the dressing forceps and dilate. It was good practice to insert the little finger and break down partitions, insert a drainage-tube and apply the dressing. There was a form of glandular swellings, occurring oftener in adults than in children, in which neighboring glands broke down one after another. Here he found it quicker and safer to dissect out the whole mass while treating the first abscess. If pus came in contact with the wound, do not close it at once, but pack for three or four days with iodoform gauze, then if the wound were in good condition, remove the gauze and suture.

Chronic forms of glandular swellings varied in their degree of acuteness, and should be treated accordingly. If they occurred in connection with diphtheria, scarlet fever, etc., strict attention must be given the mucous or cutaneous surface from which absorption had taken place. If pus were present in the gland, it should be evacuated.

Speaking further of the treatment of chronic glandular affections, Dr. Gerster said he thought all glandular troubles might be divided profitably into two classes; one in which the positive element was pyogenic infection, the other in which tuberculosis was the cause. In the first class, proper treatment directed to the exciting factor would often effect a cure, especially if aided by local measures. The ice-bag was of benefit, applied early; it might do harm after pus had formed, and at this stage patients usually found it uncomfortable. There was a time when we could not decide whether suppuration had taken place or not, and here he found the application of a poultice to be proper.

In chronic forms of lymphadenitis of pyogenic origin great disfigurement sometimes resulted when they were left to the tender mercies of nature; in girls, where the cosmetic effect had to be considered, the surgeon could do much to prevent disfigurement by aspirating the abscess, and washing it out on different occasions until it ceased to refill. Usually four or five times answered. In children whose general condition was growing lower from the presence of chronic suppurating lymphadenitis, he dealt radically with the source of infection; reopened the abscess and scooped away the pyogenic tissue.

In the case of tubercular glands in children, one might think there was suppuration and fluctuation when there was not. Aspiration would decide. He believed that all forms of tuberculosis in the human body were spread through the intervention of the lymphatics; that the glands became the deposit of the germs, and from there they spread. An early diagnosis was not always possible, but where the glands became solid he looked upon it as a warning note and removed them if it could be done with safety to the patient. If allowed to break down, and communication took place with the air, hectic would develop, blue tissue would be seen, ugly scars form. The blue, non-viable tissue, should all be removed by scissors and forceps and adjacent enlarged glands be extirpated. He emphasized the importance of cleanliness in all operations, particularly in aspirating and washing out glandular abscesses.

Dr. B. F. Curtis thought that in cases of glandular enlargements of the size of a hen's egg to the size of the fist there was ground for difference of opinion as to treatment. Those surgically inclined would probably use the knife; those medically inclined would probably try medicine. He agreed with Dr. Gerster, that both means should be employed. Encouraging surgical treatment was the danger of tubercular infection. The size of the tumor would have considerable influence, particularly in children, who bore loss of blood and prolonged operations poorly. Every case had to be decided on its own merits, but the majority of the doubtful cases would eventually, he thought, fall to the surgeon.

Relative Frequency of Adenitis in Childhood.—Dr. W. W. Vanarsdale said he had treated about fifty-five cases of lymphadenitis in children the past year, including all kinds excepting syphilitic ones. The percentage of cases of cervical adenitis in children had been twenty-three, in adults, 7.7. But where the diagnosis had been made of tubercular adenitis there had been a greater number of cases in adults—six per cent. in children, eleven in adults. Of what had been spoken of during the evening as chronic septic adenitis, twenty-one per cent. of the cases had been in children, against twelve per cent. in adults.

Dr. Henry Koplik had found that half the battle in treatment consisted in diagnosis. Regarding etiology, there were some cases in which it was somewhat uncertain, especially those called benign adenitis. Here the glands did not become very large, and after the acute attack had passed away, still remained large, belonging, perhaps, to the class spoken of as hyperplastic. They were not tubercular, caused no trouble, but for cosmetic reasons their presence was objected to by parents and patients. Dr. Koplik drew special attention to syphilitic lymphadenitis, which up to the present had received comparatively little discussion. The etiology was important in connection with treatment. He thought scrofulous and tubercular cases might well be grouped together. They gave about the same picture, although in both the tubercle bacillus might not sometimes be found.

Officers Elected.—*President*—Dr. A. L. Loomis; *Vice President*—Dr. E. L. Keyes; *Trustee*—Dr. F. A. Castle; *Treasurer of the Trustees*—Dr W. F. Cushman; *Committee on Admissions*—Dr. C. C. Rice; *Committee on Library*—Dr. C. A. Powers. A number of nominees had withdrawn.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

DR. STEPHEN MACKENZIE ON ANÆMIA—THE ARTIFICIAL CULTIVATION OF TUBERCLE BACILLI—RECENT APPOINTMENTS AT ST. BARTHOLOMEW'S HOSPITAL—DEATHS OF MR. JOHN MARSHALL AND OF MR EDWARD BELLAMY.

LONDON, January 10, 1891.

ON Monday evening last Dr. Stephen Mackenzie commenced the delivery of the course of Lettsomian Lectures at the Medical Society of London, taking for his subject, "Anæmia: its Pathology, Symptoms, and Treatment." After discussing the composition of the blood, under the two heads of "plasma" and "formed elements," Dr. Mackenzie proceeded to consider the sources, life-history, and fate of the red blood-corpuscles. The spleen, he said, appeared to have (in the human subject) a limited capacity of blood generation in extra-uterine life. Referring to the divergent views on the subject, he said that much of the difference of opinion that existed had arisen from the kind of animal that had been the subject of experiment, for the relative share taken by the cytogenic organs in blood-formation differed considerably in different classes. As to lymphatic tissue, it had long been held that—whether arranged as glands or occurring in patches of adenoid connective tissue—it was the chief producer of colorless corpuscles. It was also thought that lymphatic glands might have the power of transforming colorless into red corpuscles, but that this power, if it existed, was very sparingly exercised in general was evidenced by the well-known characters of lymph. It was, however, possible that when lymph was delayed in its channels it might bring about the conversion of leucocytes into red corpuscles. It had recently been suggested that the thyroid body, if not in ordinary circumstances a blood-producing organ, might take on this function when all the latent capacity of blood-formation of the organism was called into play. The evidence on which this opinion was based had been shown by Gibson to be very meagre and inexact, and the lecturer thought it might be accepted that the thyroid gland had no hæmopoietic functions. He summed up the sources of blood-formation by remarking that it practically amounted to this: That in post-embryonal life the red blood-corpuscles had their birthplace in the marrow, though a slight power of hæmogenesis might exist in the spleen, and possibly in lymphatic structures.

Turning then to the other end of the life of the red blood-corpuscles, Dr. Mackenzie observed that the life of every cell was limited, and the red blood-cell was no exception to this universal law. We had abundant indirect evidence of destruction of red corpuscles in the formation of bile, the pigment of urine, and other pigments derived from hæmoglobin. Quincke had estimated the average life of a corpuscle to be about two weeks. The most active destruction appeared to take place in the portal system of blood-vessels. As to the colorless or white corpuscles (leucocytes), Dr. Mackenzie remarked that among the important advances in our recent knowledge of the blood, was the recognition that the colorless corpuscles differed much among themselves—certainly as regarded their morphological characters, and probably as regarded their physiological functions. Beside the red and colorless corpuscles, the blood also contained some smaller formed elements, concerning the origin, nature, and functions of which there were as many theories as the bodies themselves had received names. The so-called "invisible corpuscles of Norris" had been proved by the researches of Messrs. Ernest Hart and Gibson to be red corpuscles decolorized by the method of preparation.

The functional activity of the blood depended upon the amount of hæmoglobin contained in the red corpuscles. Osler had well summarized the variations which took place in the hæmoglobin contents of the red corpuscles as follows: 1. In chlorosis, the hæmoglobin was reduced out of proportion to the reduction of the corpuscles, so that the individual worth of each red corpuscle in coloring matter might be greatly lowered. 2. In ordinary anæmia from hemorrhage, or from organic disease, the average worth in hæmoglobin of each corpuscle usually remained unaltered, and the percentage of coloring matter corresponded with the percentage of the corpuscles. 3. In certain cases of pernicious anæmia, the interesting fact had been ascertained that the percentage of hæmoglobin was increased, and the anæmia was thus in reality not so great as the reduction in the number of corpuscles would appear to indicate.

The classification of cases of anæmia which had been adopted by most writers on the subject was into: 1. Secondary and symptomatic anæmia; 2, primary and idiopathic anæmia. The lecturer said he considered that all cases in which anæmia was not symptomatic should be regarded as idiopathic. The latter term was, as was well known, first employed by Dr. Addison for that particular form of anæmia of which he gave such a masterly description. It had been argued that the term should be restricted to the class of cases described by Addison. Dr. Mackenzie urged, however, that the progress of our knowledge rendered it advisable to enlarge its meaning so as to embrace all primary anæmias, and to use it as a generic term including several species. Of these species, two were well defined—chlorosis, and the form described by Addison, which had by common consent come to be called "pernicious anæmia," and which name, he thought t was now useless to oppose. Probably there were other forms of idiopathic anæmia to which he should have to allude in subsequent lectures.

At the last meeting of the Pathological Society, Sir Hugh Beevor showed several tubes containing cultivations of tubercle bacilli in different media. On potato, the growth first became visible in from twenty to thirty days, but the growth did not progress so well as on other media; the cultures were kept at a temperature of 82° F. In the cultures in broth, both with and without glycerine, the growths started more quickly than on agar-agar or on potato, and further, in glycerine broth cultivations could progress, though only slowly, at as low a temperature as 60° F., whereas, on potato and on agar-agar no growth could be obtained at this temperature. The addition of corrosive sublimate in the proportion of $\frac{1}{200000}$ to broth, had hardly any deleterious effect on the growth of the tubercle bacilli, whereas $\frac{1}{300000}$ would prevent the development of the bacillus of anthrax. On agar agar without glycerine it was very difficult to get tubercle bacilli to start, but when glycerine was added, the growth was most luxuriant at suitable temperatures. From his observations, Sir Hugh Beevor said he considered it probable that the conditions in nature under which the tubercle bacilli could flourish were much more diversified than had been previously suspected.

Somewhat unusual events have recently taken place at St. Bartholomew's Hospital and have caused some comment, considering that the hospital is one of the largest in London and the medical school attached to it is the largest of any of the metropolitan schools of medicine. Although the Physician Accoucheur (Dr. Matthews Duncan) died last autumn during the vacation, no steps have been taken to fill the vacancy thus occasioned until quite lately. In the meantime the Assistant Physician Accoucheur resigned, thus creating a second vacancy. The senior appointment has been filled by the election of Dr. Champneys, hitherto obstetric physician to St. George's Hospital The junior appointment has been provided for by promoting Dr. W. S. A. Griffith, the obstetric tutor. To go to another hospital to obtain a physician accoucheur is not absolutely unprecedented, as witness the example of Dr. Robert Barnes, who held a similar appointment at three hospitals in succession, viz., The London, St. Thomas's, and St. George's. The circumstances, how-

ever, are certainly unusual, as in most cases such a procedure is adopted only when there is a dearth of local talent. Dr. Champneys has made his mark as an obstetrician, and is an old pupil of St. Bartholomew's, but his "translation" from St. George's will come as a surprise to many.

Among recent deaths I have to chronicle those of Mr. John Marshall, President of the General Medical Council and formerly President of the Royal College of Surgeons, and of Mr. Edward Bellamy, senior surgeon to Charing Cross Hospital and the namesake of the author of "Looking Backward."

AMPHITHEATRE OPERATIONS.

To the Editor of the Medical Record.

SIR: Referring to Dr. Newell's remarks in your issue of the 17th inst. upon "Amphitheatre operations," allow me to suggest that in cases where it is important to have such operations, together with aseptic conditions, a plate-glass chamber could be constructed for use in the larger amphitheatres, which could be made thoroughly aseptic, and could be warmed, and ventilated with sterilized air.

In such chamber an operation could be performed before a class without harm from septic sources to the patient, with as good opportunities for observation as are now possible to most of the members of a large class. Such a chamber could be constructed so as to be placed in position or removed at will. Its floor and walls two or three feet high should be metallic, as should also the door, and the upper portion, consisting of glass, could be so constructed as to be placed in position or lifted and remain suspended when not in use.

Yours truly,
RICHARD DEWEY, M.D.

Illinois Eastern Hospital for the Insane.

TREATMENT OF INGROWING TOE-NAIL.

To the Editor of the Medical Record.

SIR: In your issue of January 3d, you published a review of Wood's "Medical and Surgical Monographs" for 1890, and of the "Treatment of Ingrowing Toe-nail." You say: "The method described is that of Dr. Th. Anger, and consists in the removal of an oblong piece in such a way that it includes all the diseased tissues, exuberant ulcers, the border of the nail, and the corresponding matrix, at the same time leaving a flap to cover the cut surface, and shorten the period of healing by granulation. In that, the operation has an advantage over that of cutting, of which the author seems not to have read."

Though I have read the descriptions of the operations referred to, and many others, I believe the following procedure will be found preferable, for the ensuing reason. The operation is painless and bloodless, and the cure is almost immediate. My first case, which was operated upon more than seven years ago, was a baker about thirty years of age. He had been lame a few years, owing to the painful condition of his toe. He would not submit to any operative interference requiring an anæsthetic. I convinced him that the procedure proposed would not pain, and that he could interfere at any time, if he wished to do so.

The diseased toe was washed with a two and a half per cent. carbolic solution as well as the pain would permit. With the point of a scalpel, the nail was cut through, from before backward, along a line parallel with, and about 5 mm. from the visible lateral border, on the affected side. While cutting through the nail, and everting the offending segment, so as to keep the cut as broad as possible, the matrix was cut away (or rather scraped away) from the under surface of the segment with every stride. Having arrived near the root of the nail—cutting, everting, and scraping—the direction of the cut in the nail was continued at a right angle down to the imbedded lateral border, the nail being dissected from its bed meanwhile. In rounding this corner, the patient complained, for the first and only time, of a momentary sting, as if pricked with a pin. The forceps were then applied to this corner, which was turned outward or everted, and the segment, having been loosened from its attachments in the inflamed groove, was drawn out. The end of the segment removed, where it had projected into the pulp of the toe, so as to be palpable under the skin in front, was gangrenous.

The ulcerated wound was washed out with carbolic lotion, and the toe wrapped up in absorbent cotton. This was the entire dressing. He put on his shoe immediately, and walked fairly well. The next morning he was seen running down the hill to his place of business. Until the day he died, five years later, he never suffered from that toe again. I have had many opportunities for testing the above procedure, and have found it even more gratifying in the immediate results than in the above case.

If a shoe be chosen that will not press on the side of the toe, to such an extent as to crowd the fleshy portion over on top of the nail, and the corner of the nail is kept trimmed, no relapse will occur. I believe I have abundant evidence for that fact. As little of the sound portion of the nail as possible should be removed. The flatter and stronger the nail is, the better; because any attempt at thinning the nail only weakens its resistance to the oppressing phalanx, and, thereby increasing the curve, drives the lateral borders deeper into the fleshy grooves at the sides. I have never attempted this procedure in any of my dispensary clinics, for the patience and time requisite are more than consistent with the routine of such a place.

It is sometimes difficult to persuade a patient that the knife, scissors, and forceps will not hurt him; but by agreeing on a fee equal to that for reducing a dislocation, and then promising a painless, bloodless operation at the risk of the fee, the work is soon begun. He must be impressed with the fact that he must complain the moment he is hurt, or never.

The patient, in my experience, after smiling and grinning his approval and satisfaction during the operation, puts on his shoe, prances up and down the floor (at my request) to be convinced of the relief obtained; and then, with surprising alacrity, he exultingly produces his fee. This I have ever looked upon as the best indication of the immediate success of the method. Unwilling to enter at present into further details, the literature, and theories of the subject, I submit the above to your consideration. Yours very truly,

J. J. E. MAHER, M.D.

New Instruments.

AN ANTISEPTIC SYRINGE FOR HYPODERMIC INJECTION.

By JOHN BLAKE WHITE, M.D.,
PHYSICIAN TO CHARITY HOSPITAL, ETC.

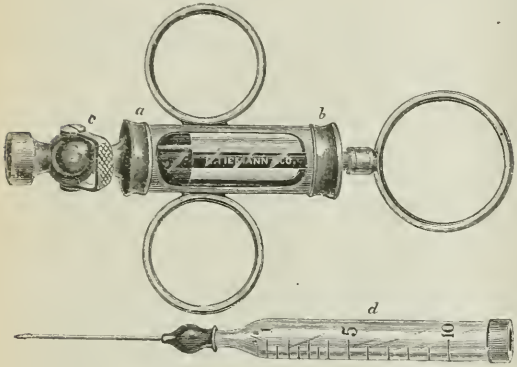
SINCE the first introduction into practice of hypodermic medication by Dr. Alexander Wood, of Edinburgh, this swift, sure, and economic method of obtaining the effects of remedial agents has grown steadily and justly into favor. Though this resort has been so long in use, and the numerous imperfections about the means employed so fully recognized, no attempt has hitherto been made to remedy defects. Meantime the great science of bacteriology has arisen, and in its marvellous advance is making peremptory demand for the institution of safeguards around the direct introduction of agents into the blood by subcutaneous injection.

Everyone abreast with the pathological discoveries of

the day, and therefore necessarily interested in antiseptic medication, will doubtless welcome into use the improved hypodermic syringe with antiseptic attachment herewith prefigured.

The important advantages claimed for this over other instruments of its kind must be manifest to everyone at a glance. No elaborate description therefore appears necessary in this act of first bringing it into notice.

The most striking peculiarity about this instrument consists in the fact that, in order to draw up fluid into the syringe for hypodermic use, the act of suction is accomplished in an independent air-chamber attached, *b*. These two chambers or barrels are so precisely adapted in capacity to each other, that ordinary use of the piston in the upper or suction barrel *b* can never cause surplusage of fluid in the lower barrel, or syringe proper *d*. Thus the important feature of keeping the fluid contents of the syringe free from contact with, and from possible contamination by, the piston is insured.



It will be further noted that the two barrels *b* and *a* are distinctly separated by the neat interposition of what may be described as a purifying chamber *a*, attached to which is a new and convenient form of stop-cock *c*. Through the antiseptic chamber *a* all air concerned in the mechanical working of the syringe is forced to pass a minute filter, which is kept impregnated with one of the several recognized and effective antiseptics. There is no want of proof that more or less grave consequences are likely to ensue from admission into the system of even the minutest atom of air containing septic micro-organisms. The antiseptic chamber *a* is therefore placed between the two barrels to intercept zymotic germs, which are apt to intrude from countless sources, and so prevent their entrance into the circulation through the act of hypodermic injection.

The lower barrel of the syringe *d* can be readily detached from the rest of the instrument in order to cleanse it, and this cleansing process after use is of too great importance ever to be omitted.

The original device described above is the one I am in the habit of employing in the frequent introduction of my particular forms of hypodermic and intra-pulmonary injections, and I certainly have every reason to appreciate more and more its manifold advantages.

Sundry conveniences of a novel character about the construction of the case in which the instrument is contained, cannot fail to claim approval. I invite attention to them, as they, no less than the very unique instrument, reflect great credit upon the artists who have so faithfully put my designs into execution.

1013 Madison Avenue.

Another Medical Society Wanted.—According to some Western medical journals there is great need for another medical society in or near Chicago, the present one being notoriously inadequate to the wants of the profession.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 18, 1891, to January 24, 1891.

Ives, Francis J., Captain and Assistant Surgeon. By direction of the Secretary of War, relieved from temporary duty at Pine Ridge Agency, S. D., to take effect when his services can be spared by the Commanding Officer of the troops there stationed, and will then return to New York City and resume his leave of absence. S. O. 17, par. 9, A. G. O., Washington, D. C., January 21, 1891.

Gardner, Edwin F., Captain and Assistant Surgeon. By direction of the Secretary of War, relieved from duty at Pine Ridge Agency, S. D., and will proceed without delay to Fort Riley, Kan., and report for temporary duty to the Commanding Officer of that post. S. O. 17, par. 10, A. G. O., Washington, D. C., January 21, 1891.

Official List of Changes in the Medical Corps of the United States Navy for the week ending January 24, 1891.

Persons, Remus C., Surgeon. Ordered to the Concord, February 10th.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 24, 1891.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	10	3
Scarlet fever	146	20
Cerebro-spinal meningitis	1	1
Measles	453	33
Diphtheria	103	22
Small-pox	0	0
Varicella	13	0
Pertussis	3	17
Croup	0	0

Mortality in European Armies.—Some curious details have just been published on the relative mortality among European troops during time of peace. The Spanish troops give the highest standard of mortality, and that not because the soldiers are weakly so much as that the sanitary arrangements are inadequate or neglected. The deaths represent 13 in 1,000. Russia comes next; but the interval is large. The mortality is about 9 in 1,000. Then follow the Italians, with 7.74. So far the series is almost as a shrewd observer might guess it would be. What follows is more perplexing and more interesting. Austrian, French, English, Belgian, and German—that is the order. In round numbers, the deaths of Austrian soldiers are in the 1,000, 7; of French, 6; of English, a little over 5; of Belgian, a little over 4; and of Germans, a little under 4. The ravages of consumption are enormously greater in the case of English soldiers than of any other nationality, and in this case the French are the most favored.—*Hospital Gazette.*

Compulsory Treatment in Hospital.—The *Times and Register* states, that Judge Thayer, of Philadelphia, says that no person can be legally compelled to leave his home and be treated in a hospital, even if he have small-pox or other contagious disease; it is the right of the patient to stay in his home, if he so desires. It is reported that, through ignorance, physicians sometimes aid in compelling patients to leave their homes.

THE NEW YORK ACADEMY OF MEDICINE—WHAT IT IS AND WHAT IT MAY BE.

INAUGURAL ADDRESS.[1]

BY ALFRED L. LOOMIS, M.D.,

NEW YORK.

FELLOWS OF THE NEW YORK ACADEMY OF MEDICINE: When, two years ago, my distinguished predecessor introduced me as your President-elect, I stated that history alone must say with what degree of success the work which he had so ably begun will be continued. As a slight contribution to that history, permit me to briefly review the records of these two years.

On assuming the presidential chair I found your trustees already in possession of a building fund of $98,300, a fully organized Subscription Committee at work to increase this sum, and a Site Committee appointed by the Council, whose reports of available locations, however, had been met by such diverse opinions that no decision had been reached. The unanimous recommendations of a second committee, which had been appointed by the Council in November, 1888, whose field of search had been limited to the twenty blocks above Thirty-fourth Street between Park Avenue and Broadway, in favor of the present site of our building, met with unanimous approval as early as December 7, 1888. Yet it was only after many discouragements, with great vexation of spirit, and considerable pecuniary loss to some members of the committee and their personal friends, that, on February 26, 1889, the Council ratified the purchase of the present site for $90,000. Ten days later, on March 7th, the formal approval of the Academy was recorded, and at a meeting of the Council, on the 26th of the same month, Drs. Jacobi, Herrick, Peters, Castle, and your President were appointed a Building Committee, to whom all details of the work were to be referred. The organization of this committee, which was completed at their first meeting by the election of Dr. Loomis as chairman, and Dr. Castle as secretary, was followed immediately by an invitation extended to Messrs. J. C. Cady, C. C. Haight, and S. R. Robertson, architects, to submit plans and elevations for a new Academy building. This invitation of March 27th met with such prompt compliance from these gentlemen, that within less than a month the Committee had made such careful comparisons of the submitted plans, under the personal demonstration and explanation of their respective authors, as to reach a unanimous approval of those presented by Mr. S. R. Robertson, and upon April 15th we were permitted to indulge in mutual congratulations upon the appointment of Mr. Robertson as architect of the new building.

A second month was consumed in the preparations of specifications, in suggesting desirable changes in plans, and in arranging contracts, until, upon May 7th, with all contracts signed for a sum-total of $149,000, pick and spade made the first stroke in the work, the completion of which we have so recently celebrated in the dedication of this building. The 15th of July witnessed the fixing of the first foundation-stone, and on the 2d of October, 1889, we had the pleasure of formally laying the corner-stone, assisted by some of the most distinguished laymen of our city.

The sale of the old Academy building for $60,000, early in May, 1890, necessitated the removal of our Library before the completion of our new building; but as the stack room had been completed and rendered safe for its reception, its removal was accomplished during the latter part of the same month. Notwithstanding the many last things that always arise in connection with such a work, and the annoying details and disappointments which seem to be unavoidable, the building was finally completed, at a total cost of $151,000, within eighteen months from the commencement of the excavation.

Several meetings had been held in the new building before this—the first being that of the New York Pathological Society, on September 24th. The first general meeting of the Academy in its new building was held on October 2d, just one year from the date of laying the corner-stone, and to Dr. Charles McBurney belongs the honor of having presented the first paper read before the Academy in its new building. Although regular meetings have been held since, it was not until November 20th that the building was thrown open to the public, at a general reception, and assumed its position as the headquarters of the medical work of the city.

Notwithstanding the confusion of house-moving, the Academy has missed but one meeting, while at the thirty-five meetings that have been held during the past two years sixty-five papers have been read and received valuable discussion. This work of the Fellows has been of a high order of merit, and has done much to increase the already enviable reputation of this body for thorough scientific work. A most gratifying feature of recent years has been the increasing number of the younger members who have manifested not only by their regular presence at the meetings, but by participation in the discussions and willingness to contribute to the scientific work, an unusual interest in the welfare of the Academy—an interest which promises that the future shall find earnest and faithful men to whom the honor and well-being of this Fellowship will come as sacred trusts.

Within this same space of two years the various sections of the Academy have held over one hundred meetings, at which more than that number of papers have been read and discussed. Such a record shows a marked increase in the amount of work being done in this Fellowship. An especially pleasant feature of the past year has been the assumption by each Section, in order, of the charge of one regular meeting of the Academy each month. Such a course has brought the Sections into closer relationship with the Academy, has stimulated them to more careful work, and excited a keener interest in the regular Section work.

It is to be hoped than an honorable ambition and generous rivalry will incite them to present the best work of the year when they appear in the general meeting of the Academy.

Our numerical growth has been equally marked in all directions, one hundred and thirty-five resident members have been received into our Fellowship, while the reaper's sickle has taken but few of our number. Nearly two thousand volumes have been added to our reference library, in addition to the ten thousand and odd numbers of medical journals which have passed through our reading-room each year. A conservative estimate of the property of our Academy to-day makes its value not less than

[1] Delivered at the meeting of the New York Academy of Medicine, February 5, 1891.

$4co,ooo, of which $280,000 is in real estate, $70,000 in library, $15,000 in furniture, and $33,000 in invested funds. Against this we have a debt of only $30,000, with a membership of seven hundred resident Fellows.

With such a present, what should be, what must be, the record of the two years upon which we enter to-night?

Both '91 and '92 will bear the stamp of what *we* do.

Opportunity implies obligation, and power develops by direct evolution into action. We cannot shelter our indolence under the cloak of yesterday's successes. Seven hundred earnest, faithful physicians should form a centre of power in all matters pertaining to the health of this city and State that no civil authorities could withstand.

If this Academy could find in every member a firm and loyal follower of its standard, ready to uphold it, both in this hall and in public, ready to advocate its claims to be the authority, in matters medical, among all his patients and friends, the time would not be far distant when we could send our representatives to the halls of legislation, and demand, in the name of the people, that this must be done, and the other left undone.

We do not make such claims in arrogance, but in the just consciousness that the medical man knows no party or politics, and that he has gone beyond even the fundamental principle of our Constitution. We demand not "the greatest good for the greatest number," but "the one good for all." That we may the more effectually assume this position this Academy must be not the best representative of medical men in this city, but it must be *the* representative of *all* medical men.

In my address two years ago, I spoke of the diffusion of forces among the profession, and the misfortunes attendant upon the attempt to cover many fields. There is no need of argument to prove that all the medical talent and scientific work in our city should be centralized. With an average of more than three meetings each week, distributed among twelve Sections, in addition to the general meetings, abundant opportunity is certainly offered for the presentation of all the valuable work that finds outlet in this direction. Nor is even this our limit of growth; we offer a home and a parent's fostering care to those who are interested in any special branch of medical work. Is it not more creditable to be a vital and valued member of one grand herculean organism, than an isolated and powerless unit, a Liliputian anatomy?

Would not the Pathological Society, for example, be more honored in being the Pathological Section of the Academy, than remaining an independent organization? It would by such a union not lose its character as a body devoted to special research, but it gains the honor of being a necessary part of a great scientific whole. Such changes imply, of course, the putting aside of self, the doing away with little bitternesses and anger, malice and clamor, and rising to that higher plane and purer air where the cry of pain and anguish are our bugle-calls to duty, and honor and human sympathy become stronger than self. The jealousies and intolerance of cliques is fast giving place to liberality and good-fellowship. The links which bind us together are being forged with greater strength, every Fellow is realizing more and more that there is resting upon him the good name and fair fame of our Fellowship, and that he should bear himself with greater pride that such high privileges have been intrusted to his care.

It is told of the Greeks that they arranged their soldiers in families, for then each man fought not for Greece alone, but for his friends, counting it joy to give his life for those he loved. If friendship makes better soldiers, duty as well as inclination bids us to be better friends. Let us then cultivate more largely friendly relations with each other by frequent social intercourse. To this end it seems to me exceedingly desirable, and I would propose, that one evening each month, in addition to our regular meetings, or, if it seem better, a portion of our regular meeting each month, shall be set apart for this special purpose.

While both recognizing and urging the expansion of our activities in every appropriate direction, I desire to suggest two advances which seem most plainly to demand immediate attention. In the practical line there should be established by the Academy a Nurses' Bureau, where only reliable and carefully selected persons should be allowed to register. It is not fitting that personal gain should be the basis of such registration, as the personal experience of every Fellow must convince him is the case in most of the existing nurse agencies. An examining committee from our Fellows should be appointed, to systematize, control, and decide all matters relating to such a Bureau. The other and more important advance which I desire to propose is the establishment of a volume of "Transactions" of the Academy. Such a volume should consist of the aggregation of monthly issues of a bulletin somewhat after the plan adopted in the *Johns Hopkins Monthly Bulletin*, such bulletin to be edited by a competent corps of Fellows, and conducted upon such an impartial basis as to afford a permanent record for all the best work done in our Fellowship—a filter to protect the hurried practitioner from wearying himself with simple recitation and useless speculations. I am convinced that such a paper, issued under the authority of this body, would not only receive such support from the profession as to make it sustaining, but what is of far greater importance and value, would afford such honorable recognition of merit as to stimulate every worker among them to sift his own work more carefully to make it all of higher value, and to present publicly only what is fully worthy of a permanent place in medical literature. All these advances imply labor, and, in a measure, a labor of love. But here, as elsewhere, the past gives pregnant promise for the future. The quiet peace of these halls, the stately beauty of this building, give more lasting praise than words can do to those who have borne the heat and burden of the day; a praise that is justly due to all who have taken part in this work, and which must stand as more or less of a reproach to those who have contributed neither silver nor sympathy; but who now come to enjoy the results with all the complacency of fellow-laborers, even while the confession is on their lips, "This is the first time I've seen the building."

To the faithful ones my public expressions of praise can be of but little value, yet for justice' sake, if for no other, this acknowledgment of their service is due to all, and especially to Dr. F. A. Castle, whose faithfulness to detail, as well as comprehensive grasp of the whole work; whose patience and perseverance, whose indefatigable activity and hard work, have done more than any one to make our house a home. Nor can I fail to acknowledge the deep obligation we owe to Mr. Robertson, our architect, who has not only given us his best thought in planning our new building, but by his painstaking care and judgment in awarding contracts assumed the unusual labor of both architect and contractor, and by so doing has diminished by many thousand dollars the cost of our building.

And now for the years that are before us. Shall the Academy be the power which is to elevate our profession to a higher social and intellectual plane than it has reached in the past? Shall it take the lead in the many rapid transformations that are taking place in every department of science? Shall it be the guardian to preserve and sustain an ideal medical spirit in the profession of our city, or shall it be simply a mutual admiration society for the delectation of the few.

It will be, gentlemen, what you and I make it. If we hope to utilize the great privileges and benefits which have come to us, and do our duty to ourselves, our profession, and the commonwealth, we must realize that words are not work, that talk is not truth, that fancies are not facts.

Let every Fellow remember that great gifts demand great returns, and that the Academy stands ready to mete out with equal hand both rewards and reproofs.

Thanking you, gentlemen, for this second honor, and feeling that I can better express my appreciation of your unusual confidence by action rather than by words, I pledge that my earnest and best efforts shall be exerted in the future, as in the past, for the welfare of our Academy.

PURPURA HÆMORRHAGICA.

By GEORGE ROE LOCKWOOD, M.D.,

NEW YORK.

As ordinarily described, purpura hæmorrhagica, or morbus maculosus, is a disease characterized by spontaneous hemorrhages, not only appearing subcutaneously as in simple purpura, but also from the mucous membranes, and more rarely into the serous membranes, internal organs, and joints. This disease was first described by Werlhof, in 1775, and is known as Werlhof's disease.

The patient usually presents prodromal symptoms which may precede the actual onset several days or weeks—malaise, chilly sensations, loss of appetite, and possibly a little rise of temperature being the prodromata most commonly seen. In other cases the disease begins abruptly.

When the disease is fairly developed we have appearing a purpura, the spots varying greatly in size, usually appearing upon the extremities, though they may be generally distributed. There are hemorrhages from various mucous membranes—from the nose, mouth, bronchi, stomach, intestines, and kidneys. These are usually moderate in severity, but may be profuse enough to endanger the life of the patient. There are usually constitutional symptoms, chilly feelings (rarely amounting to a rigor at the onset), fever of slight intensity, loss of appetite, and prostration. The gums are normal or slightly swollen, they may bleed, but the teeth are not loosened as in scurvy. The liver and spleen are slightly enlarged; there may be pain and swelling of joints, as in peliosis rheumatica.

Such a disease runs a course of two to four weeks, and tends toward recovery, though relapses are to be expected, and by these relapses the disease may be protracted weeks, months, or years.

In some cases in children the disease manifests itself by purpura, pain and swelling of joints, abdominal pain and tenderness, with tenesmus and bloody stools. It is characteristic of this form of the disease for the patient to suffer from a number of these attacks at short intervals.

Letzerich, in a recent monograph ("Ætiologie und die Kenntniss der Purpura Hæmorrhagica, 1889"), has given us a careful bacteriological study of the disease. He had attended a girl, twenty-five years of age, suffering from Werlhof's disease, in whom a generally distributed purpura, hemorrhages from intestine and kidney, slight fever, prostration, enlargement of liver and spleen were the symptoms noticed. Bacterial examinations carefully performed showed in the purpuric spots the presence of long bacilli capable of growth in gelatine, the pure cultures of which injected into the abdomen of rabbits reproduced the original clinical symptoms in all of twelve cases, and in these the same bacilli were found, identical with those of the pure cultures injected. An examination of the purpuric spots in the rabbits showed dilatation of the capillaries, emigration of white cells, and rupture of the capillary wall allowing of escape of red cells. The capillaries were found filled with the bacilli, with abundant spore growth. (The bacilli and spores had been previously noticed by Petrone, who considered it to be a mixed infection.) Upon squeezing the section little plugs resembling hyaline casts, containing bacilli, emerged from the capillaries, and these structureless casts he considered as the result of the action of the bacillus or its products upon the fibrino-plastic elements of the blood.

Very remarkable was the appearance of the liver in these rabbits. The organ was regularly enlarged, the portal capillaries were almost occluded by an extraordinary growth of the bacilli. Letzerich considers the liver to be the breeding-place of the bacilli in Werlhof's disease, the liver being to this disease what the spleen is to malarial fever. If he be correct in this view it helps explain both the scattering of the lesions—a bacterial embolism of the capillaries—and also the tendency of the disease to relapse, as well as the periodicity of the relapses seen in some cases. Letzerich himself was attacked by the disease, from which he with difficulty recovered. He attributes his infection to handling his cigar while working at his experiments. The results of other experimenters before the time of Letzerich do not stand the tests of modern requirements and must be excluded.

Aside from these cases in which the disease runs this mild course, we meet with cases in which the same symptoms are present, but in an acute fulminating form. The patient is overwhelmed by the violence and the rapidity of the symptoms, and dies from acute anæmia, internal hemorrhages, or from symptoms of a septic infection. These cases are but briefly referred to, if at all, in the text-books, and it is to these that I would invite your attention. Great care was taken in the selection of these cases to exclude the other forms of hemorrhagic disease to which mention will presently be made.

The first case I have to report is that of a young lady, aged nineteen, living in affluent circumstances. For several years past she had suffered from a moderate degree of anæmia, and at one time was said to have had malarial fever. There was no other previous morbid history. Her father, when a boy, would bleed severely from slight causes, but further history of hæmophilia could not be obtained. Her illness began on March 7th, though for several days previously she had been ailing from a slight laryngitis.

On March 7th, at 1 A.M., she was seized by a chill and appeared very nervous, the temperature remaining normal. She was given quinine (gr. x.) and remained without symptoms till 12.45 P.M., when she had another chill, the temperature being 101.5° F. during the chill, rising to 103.5° F. within an hour, and then slowly sinking to normal. Shortly after this second chill she was attacked by a nose-bleed, which increased in severity till, by 9 P.M., it had attained an alarming profuseness. Applications of ice, hot nasal douches, insufflation and injection of styptics were vigorously employed; but while each seemed to relieve for a time, the bleeding broke forth with renewed violence after each application. Turpentine and digitalis were begun internally during the night, and continued until noon of the next day.

I saw the patient for the first time at 1 P.M. on March 8th, just twenty-four hours after the acute onset. At that time she was pale and much prostrated. Temperature, 98.4° F., pulse, 130 and dicrotic. She lay in a condition of complete apathy, but her mind was clear when aroused; the expression of the face was that of a typhoid. Upon the trunk, face, and extremities were a number of small purpuric spots. The hemorrhage from the nose still continued, and there was a profuse uterine hemorrhage, although her normal period had ceased two days previously. The gums were normal, there was no fetor to the breath. The collected blood was dark in color and did not coagulate. Careful physical examination showed no evidence of endocarditis or other appreciable disease.

Post-nasal plugging was resorted to, and the anterior nares tightly tamponed and sealed with collodion, after which the hemorrhage was reduced to a slight oozing. During the afternoon she vomited about six ounces of altered blood, which she had apparently swallowed. Small doses of morphine, digitalis, and brandy were given by mouth and subcutaneously.

By evening her temperature rose to 102.8° F., her pulse varied from 120 to 180, being weak and irregular. Her somnolent condition alternated with periods of restlessness and mild delirium, while new purpuric spots were constantly appearing. Slight oozing came through the

nasal plugs; the uterine hemorrhage continued to a moderate extent in spite of careful tamponing.

Dr. L. W. Hotchkiss saw the patient with me at this time, and the question of arterial transfusion was discussed. In view of her hemorrhagic condition, and the extreme difficulty in even checking her bleeding, it was thought advisable not to add a new source of possible hemorrhage by transfusing into an artery, as an equal amount of good might result from saline injections given by rectum and subcutaneously, without danger. Her symptoms, moreover, were more septic than anæmic. Saline solutions were accordingly administered in this way, with an improvement in her symptoms, her pulse becoming slower and stronger, the stupor less profound, and her mind more clear. The improvement, however, was merely temporary. On March 9th, at 9 A.M., the temperature was 104.8° F.; pulse, 148; respirations, 28 to 32; there was no air hunger. At this time she had a black watery offensive movement composed of altered blood. During the afternoon she became more somnolent, the stupor alternating with periods of restlessness and delirium, and new purpuric spots continually appeared. The temperature rose steadily to 106.2° F.; the pulse became extremely rapid, irregular, and feeble; she passed into a condition of coma, in which she died at 2 A.M. on March 10th, two and a half days after the onset of the disease. No autopsy was permitted.

Case II. (Halbrecht, *V. & H. Jahresber.*, 1884, ii., 268).—Girl, aged ten. Spreading purpura of arms and legs, hemorrhages from bowel, with stupor, headache, and convulsions. Recovery on fourteenth day.

Case III. (Halbrecht, *V. & H. Jahresber.*, 1884, ii., 267).—Male, thirty years. After attack of urethritis developed mild symptoms of purpura hæmorrhagica; improved, relapsed, and died. Symptoms were, general purpura, bloody diarrhœa, and vomiting of blood. Whole duration three weeks.

Case IV. (Bourrieff, *Rec. de Mém. de Méd.*, April and May, 1877, quoted *V. & H. Jahresber.*, 1878, ii., 275).—Soldier, aged twenty-two. Purpura, with hemorrhages from kidney, mouth, and lungs. Died in seven hours from hemorrhages into suprarenal capsules.

Case V. (Vaillard, *V. & H. Jahresber.*, 1878, ii., 276).—Case with hemorrhages from tonsils, epiglottis, and aryepiglottic folds. Death from asphyxia. Details not given.

Case VI. (Johannsen, *V. & H. Jahresber.*, 1884, ii., 276).—Girl, aged three. Purpura, epistaxis, and hemorrhage from left eye. Recovery ten days.

Case VII. (Barthelemy, *V. & H. Jahresber.*, 1880, ii., 263).—Male, aged forty-six. Purpura, hemorrhages from kidney, stomach, conjunctiva, mouth, and nose. Death eighth day.

Case VIII. (Sautin, *V. & H. Jahresber.*, 1880, ii., 263).—Male, aged sixty. Hemorrhages from mouth, nose, ears, bladder, and rectum. Death twenty-first day.

Case IX. (Wolff, *Berl. Klin. Wochen.*, No. 18, 1879).—Male, aged two years and nine months. Purpura, fever, collapse. Death fifteen hours; hemorrhage into adrenals.

Case X. (Peszynski, *V. & H.*, 1887, ii., 350).—Male, aged forty-two years. Purpura, blood in urine, stools, and expectoration, fever. Death twenty-first day.

Case XI. (Appenrodt, *Deutsche Med. Wochen.*, No. 39, 1875).—Child, aged nine months. Purpura, epistaxis, vomiting of blood, blood in stools and urine, apathy, convulsions. Death in four days.

Case XII. (Woodbury, *Phila. Med. Times*, September 18, 1886).—Male, aged twenty-three. Purpura, hemorrhages from nose, throat, and kidneys. Death eighth day.

Case XIII. (Shand, *Lancet*, 1879, ii., p. 79).—Female, aged eight. Purpura, hemorrhages from lungs, bowels, and vagina. Recovered on ninth day.

Case XIV. (Minich, *Philadelphia Medical Times*, May 8, 1875).—Male, aged seven. Purpura, hemorrhages from nose, mouth, and kidneys, and into parotid gland. Recovered third day.

Case XV. (Masing, *Vierteljahr. f. Dermat. u. Syph.*, 1887, p. 578).—Male, aged twenty-six. Purpura and epistaxis. Died seventh day.

Case XVI. (Wagner, *Deutsche Arch. f. Klin. Med.*, Bd. xxxix.).—Male, aged seventeen. Purpura, hemorrhages from mouth and stomach, coma. Death eighth day.

Case XVII. (Wagner, *loc. cit.*).—Female, aged twenty-eight. Purpura, hemorrhages from gums and uterus for fourteen days, then sudden increase, and died on twentieth day.

Of these 17 cases, 5 were females, 10 were males, and in 2 the sex was not mentioned. The youngest case was one year (the sex not stated). The oldest case, sixty years, a male. The average age of the females was twelve years. The average age of the males was twenty-eight years.

Of the 17 cases 13 died and 4 recovered (3 being females). Shortest duration of fatal cases seven hours; longest twenty-one days; average ten days; average duration of recovered cases nine days.

The autopsies showed hemorrhages under skin, mucous and serous membranes, swelling of the intestinal glands, hemorrhages into the kidneys and muscular tissues, enlargement of the spleen, and in two cases hemorrhage into the adrenals. In one of these latter cases the patient lived but seventeen hours (Bourneff), in the other fifteen hours (Wolff) after the onset of the disease.

In a second set of cases the course of the disease is characterized by blood-effusion into the brain, death resulting from cerebral hemorrhage.

Case XVIII. (Boucher, *Bull. de la Soc. Anat.*, 1867, No. 43).—Male, aged seventeen, with symptoms of purpura hæmorrhagica. Death from cerebral hemorrhage.

Case XIX. (Hebra, quoted *Gaz. Hébdom.*, 1876, No. 19).—Male, aged nineteen, with general hemorrhages. Death from hemorrhage into the left hemisphere.

Case XX. (Huchard, *Bull. de la Soc. Anat.*, 1874, p. 172).—Male, aged seventeen. General symptoms. Death from cerebral hemorrhage.

Case XXI. (Kurkowski, *V. & H. Jahresber.*, 1885, ii., 493).—Young man. General symptoms. Death fourth day from hemorrhage into left fossa Sylvius, pons, and ventricles.

Case XXII. (Wagner, *Deutsch. Arch. f. Klin. Med.*, Bd. xxxix.).—Girl, aged three, with general symptoms. Death from multiple hemorrhages into the brain.

Case XXIII. (Wagner, *loc. cit.*).—Male, aged thirty-one. General symptoms. Death from subdural and multiple cerebral hemorrhages.

Case XXIV. (Wagner, *loc. cit.*). — Male, fifty-eight years. General symptoms. Death from subdural and multiple cerebral hemorrhages.

Case XXV. (Züelchauer, *Berl. Klin. Woch.*, 1869, No. 17).—Girl, aged two. Diarrhœa and vomiting for two days; then purpura, collapse, and death in a few hours. Hemorrhages in medulla.

Of these 8 cases 6 were males, 4 being seventeen to twenty years; 1 being thirty-one years; 1 being fifty years; 2 were females, two to three years of age respectively.

In a third set of cases when the disease attacks pregnant women it seems to run a rapid and fatal course, causing miscarriage and post partem hemorrhage.

Case XXVI. (Puech, *Annales de Gynecologie*, xvi., 1887, p. 273).—Woman, aged twenty-one; pregnant six months. Purpura for four days, then purpura spread, developed hemorrhages from nose, gums, kidney, and stomach, with fever and delirium. Miscarriage sixth day, with post-partum oozing. Died eighth day, four days after sudden increase of symptoms.

Case XXVII. (Stroganow, *Virch. Arch.*, Bd. lxiii., p. 540).—Primipara, aged twenty six; delivery at term. Purpura, collapse, slight fever, post-partum hemorrhage. Death from collapse, twelve hours.

Case XXVIII. (Phillips, *British Medical Journal*, November 13, 1886).—Female, aged twenty-one; preg-

nant six months. Purpura, colic, epistaxis, delirium, concealed uterine hemorrhage; miscarriage fifth day, post-partum hemorrhage. Death eighth day.

Case XXIX. (Phillips, *loc. cit.*).—Female, aged thirty; five previous normal labors; eight months pregnant. Purpura; miscarriage in few hours. Post-partum hemorrhage and death second day.

Case XXX. (Phillips, *loc. cit.*).—Female, aged thirty-two; seven previous normal labors. In seventh month of pregnancy, purpura, epistaxis, hemorrhage from mouth; miscarriage in three days, with placental hemorrhage. Recovery in two weeks.

When we consider these cases together, we are struck by their similarity to the class of acute infectious diseases. The absence of assignable cause, the rapidity of the onset, the multiplicity and the scattering of the lesions, the enlargement of the liver and spleen, and the constitutional symptoms out of proportion to the local lesions found, seem to prove, by analogy, the assertion that we are here dealing with an acute infection.

If we compare these acute cases with those of the ordinary mild forms of purpura hæmorrhagica, we find the identical symptoms in each, except that in the acuter forms they are more intense and wide-spread, and accompanied by more marked symptoms of a general systemic infection, and it does seem highly probable that in both forms we are dealing with the same disease, caused by the same infection in all essential features, differing only in its intensity of action.

When we are called upon to see patients and diagnose their disorders, the fact is brought forcibly to our notice that purpura hæmorrhagica is but one of a group of diseases having two essential features in common—tendency to spontaneous hemorrhages and constitutional symptoms. In typical cases each disease of this group may present a characteristic picture, so that we can diagnose it and give to it its particular name. On the other hand, we meet with cases not typical of any one disease but having features common to several; they seem like transitional forms, and we hardly know just under which category to place them. The family resemblance of these diseases is so marked that we cannot close our study of purpura hæmorrhagica without briefly alluding to its relationship to the other hemorrhagic disorders of this group. It is not within the scope of the present paper to enlarge upon these other branches of hemorrhagic disease, but merely to suggest their mutual relationship to each other, as well as to that especial form to which your attention has already been directed.

In order either to affirm or to deny any positive kinship between the different members of this group, we must know in accurate detail the etiology and the pathological processes in each, and unfortunately, until we are able to reason in this way, our conclusions must be simply conjectures and suppositions. Still it would seem well to invite discussion upon this problem, in the hope that by a free expression of opinion we may find how much of fact there is, and how much of theory, in the apparent relationships among the members of this hemorrhagic group.

In the first place, what is the relation between purpura hæmorrhagica and *scurvy?* We find in both symptoms practically identical. A longer prodromal period and a spongy and bleeding condition of the gums are often spoken of as the only points of differential diagnosis between them; but scurvy may begin abruptly, and the gums may be normal, while we may notice in purpura hæmorrhagica long-continued prodromata, with gums swollen and bleeding. It would seem as if the condition of the gums depended more upon the previous care and cleansing of mouth and teeth, and upon the general condition of the patient, than upon any direct result of the disease. As a matter of fact we call it purpura hæmorrhagica if the patient be well nourished, and scurvy if he be poorly fed and poorly housed.

The older idea of scurvy was that it is a disease of malnutrition from use of improper food, or from absence of fresh vegetables and potassium salts, or from lack of variety in food, or from bad sanitary surroundings. The recent and the more generally accepted idea is that it is an infectious disease of unknown origin. This assumption is based on the fact that scurvy appears frequently in endemics and epidemics, without apparent reason, and on the fact that while the development of the supposed infection is favored by poor food and unhealthy dwellings, these are not essential, and its severity does not seem to be in proportion to the life-degradation of its victims. This view is ably advocated by Koch in the *Deutsche Chirurgie*, Bd. xi., 1889.

If the latter view be correct, why may not the infection be the same as the infection of purpura hæmorrhagica, the symptoms being modified by the unhealthy and poorly nourished condition of the patient, and by the fact that the infection, as a rule, is continued over a longer period of time—a chronic poisoning as it were. If the results of the infection be the same in both instances, it would seem to be a matter of but little consequence whether the actual infecting cause was identically the same in both diseases, whether Letzerich's bacillus was found in scurvy, or some other bacterium, or some ptomaine found in improper food, capable of inflicting the same mischief. A burn may be caused by an electric wire as well as by a hot iron, but in both instances we call it a burn. Why not simplify, and consider them essentially the same disease, the only difference being that scurvy is more chronic in its infection and that its course is modified by its occurrence in those whose powers of resistance and recuperation are weakened by improper nourishment and unsanitary surroundings.

As regards *simple purpura*, in which we have only subcutaneous and submucous hemorrhages, we find we have to deal with a diversity of causes, in some cases apparent in others obscure and suppositious. Upon studying the effect of these various causes we find great variety in the purpuric symptoms that they excite. In some cases we have only a moderate number of purpuric spots, chiefly seen on the extremities, accompanied by constitutional symptoms of such a mild character that they frequently escape unnoticed; in other cases we have developed a striking exhibition of spreading purpuric lesions with severe general symptoms, such as coma, collapse, and even death; while in other cases we have developed the symptoms of a purpura hæmorrhagica in its most intense form. It is interesting and instructive to note that these various types can proceed from the same cause, acting more intensely upon some patients than in others, either from a maximum of cause on the one hand, or a minimum of resistance on the other.

In the first place we have drug purpura—potassium iodide, chloral, quinine, and salicylic acid being the ordinary drugs during the administration of which a simple purpura is seen. More rarely we have internal and free hemorrhages, and even death resulting, as well as grades of intermediate severity.

Analogous to these cases of drug hemorrhages are the cases which accompany or closely follow severe infectious diseases, as acute yellow atrophy of the liver, snake-bites, typhoid fever, pneumonia, and the exanthemata (so-called black measles, black scarlet fever, hemorrhagic variola). In these cases we have the various grades, from simple purpura up to an acute hemorrhagic purpura. Henoch, for example, describes a case of the severer form as follows (*Berl. Klin. Woch.*, No. 1, 1887): "A child, five years of age, had lobar pneumonia; two days after the crisis developed large spreading ecchymoses of trunk and extremities, with fever, and death from collapse in twenty-four hours." Such cases are not uncommon, and have been explained by the majority of writers as due to the secondary infection of a Werlhof disease complicating the primary infectious disease from which the patient suffered; purpura hemorrhagica, or as Henoch calls it "fulminating purpura," complicating pneumonia, or acute yellow atrophy, or an exanthem.

If a drug like potassium iodide will disorganize the blood, or render pervious the blood-vessels, so as to allow even a fatal purpura, why may not the poison of these severe infectious diseases produce the same results without supposing an added infection of another disease? It is no argument against this view that the purpuric symptoms frequently appear after the crisis, because we know that a temperature crisis does not always mark the end of the disease (as witness heart-failure in convalescing pneumonia), but only, as Fraenkel[1] has recently demonstrated, the end of the fever-producing quality of the infecting germ.

We may have hemorrhagic disease appearing either as a simple purpura or as purpura hæmorrhagica in profound anæmia, in leucæmia, and in exhausted and cachectic conditions. We do not know whether to attribute its occurrence to blood-changes, or to changes in the walls of the small arteries.

That changes in the blood-vessels can produce hemorrhage is proved by the purpura, bloody sweating, and free hemorrhages, especially of the umbilicus in the newly born infant with congenital syphilitic changes in the arterial walls. Partridge,[2] in an interesting paper read before the Practitioners' Society, describes another form of hemorrhage in newly born infants of non-syphilitic parentage, during the first ten days of life. Such a form occurred in about one per cent. of infants born at the Nursery and Child's Hospital and at the Sloane Maternity, with a mortality of sixty to seventy-five per cent. He attributes its cause to the changed condition of functional activities and the altered circulation, allowing a brief interruption of the nutrition of the vessel-walls sufficient for the transudation of their contents.

That simple blood-changes alone will not account for all the cases is also proved by the purpura and hemorrhages seen in cases of malignant endocarditis, where we suppose capillary embolism of vegetation fragments to be the exciting cause.

Fagge[3] has reported a set of cases where purpura, hemorrhages from mucous membranes, rheumatic pains, and fever were noticed in patients suffering from multiple sarcomata. It is hard to say whether these result from the profound alteration of the blood due to the malignant disease, or whether detached sarcomatous fragments become lodged in the capillary vessels, and cause their softening after the manner of emboli.

Besides these changes in the arterial walls, it is supposed that a local vaso-motor relaxation, or an enfeeblement of the wall following fright, severe emotions, or due to hysterical or hypnotic influence, may be followed by purpura and hemorrhage. Such cases are frequently reported in literature. Weir Mitchell, in discussing these cases, says:[4] "We are justified in asking whether neural conditions may not be capable of directly enfeebling the vessel-walls so as to cause them to give way under arterial pressure, or to permit of such relaxation as shall enable the globules to penetrate these parts in the manner of Waller and Cohnheim?" Just how far this weakening from neural influence can be applied to other forms of hemorrhages, the nerves being affected by organized or unorganized blood-poisoning, we cannot say.

We now come lastly, to two forms of purpura to which no apparent cause can be attributed. We call these *purpura simplex* and *purpura rheumatica*, or peliosis rheumatica. In both we have simple purpura, but in the latter form associated with pain and swelling of the joints. They have been formerly considered as distinct diseases, but of late effort has been made to associate them, it being urged that peliosis rheumatica is that form of purpura which occurs in rheumatic subjects, the joint symptoms being due to the associated rheumatism, or that it is a severer form of purpura in which hemorrhages occur in or around the joints. That the joints may be so involved in purpuric diseases admits of scarcely any doubt. The joint symptoms are seen in simple Werlhof's disease, in scurvy, in Fagge's cases with multiple sarcomata, and in many other varieties of hemorrhagic dyscrasiæ. If this be so, why consider them as separate diseases? Is it not justifiable to call purpura rheumatica an intenser form of purpura with joint lesions of a hemorrhagic nature?

If Werlhof's disease be due to an acute infection, may not some of these cases at least both of simple purpura and peliosis, be cases of a lighter form of the same infection? To support this view may be cited cases such as the following of Hervé's, which seem to occupy a middle ground between the two conditions. Hervé (quoted in "Keating's Encycl.," ii., p. 83) reports an infant aged three months, who for twenty-four hours had suffered from restlessness, malaise, pallor, rapid pulse and respiration, with mucous râles in the chest. No gastro-intestinal symptoms. At the end of twenty-four hours developed spreading purpura of legs, thighs, and abdomen, with coldness of skin and some œdema, without free hemorrhages from mucous membrane, and died in ten hours.

In summing up, the points to which discussion is invited are:

1. Werlhof's disease is probably infectious in origin, the exact infection not having been absolutely proven, though probably it is the bacillus described by Letzerich.

2. We meet acute cases of this infection, in which death results from acute anæmia, from internal hemorrhages or from sepsis.

3. Purpura simplex and purpura rheumatica are probably types of different grades of the same infection, and this infection may be the same as that of Werlhof's disease.

4. Scurvy, if proven an infectious disease, may be really Werlhof's disease modified by the surroundings and poor condition of the patient, and also by the possibility of the infection being more chronic.

5. Drug purpuras, anæmic and cachectic purpuras, purpuras in exanthemata and other infectious diseases, purpuras in newly born, in endocarditis and multiple sarcomata, as well as those of neural origin, may present all grades of severity; that we can in each determine a cause, though we do not know exactly how the symptoms are produced by this cause, whether by blood-changes or vessel-changes, or from nervous causes; but these purpuras are symptomatic and not essential, and should not be classed with purpura hæmorrhagica, or Werlhof's disease, until we are more enlightened upon this subject.

ACQUIRED SYPHILIS IN A CHILD FOUR YEARS OF AGE, PROBABLY AS A RESULT OF RAPE.

By ALEXANDER LYLE, M.D.,
NEW YORK.

Before introducing the following case, which in many respects is one of rare interest, and happily encountered very infrequently by the general practitioner or even the specialist, it may prove interesting to note the fact that of acquired syphilitic infection there are two generally recognized modes of origin, the one called direct infection, in which a syphilitic person comes in direct contact with a non-syphilitic, transmitting the disease usually by the genitals, although many cases have been seen in which the infecting material has been deposited upon the lips, tonsils, fingers, and other places; and, second, mediate infection, in which the disease is transmitted through some medium from the diseased to the healthy person. The case I now present may be enrolled under the first, viz., direct infection, for although the person, or, as we might more properly call him, "the demon in human form," who committed such a fiendish act has not yet been brought to justice, there is every reason to believe that this child was infected

at the vulva by a syphilitic penis. There is a most erroneous belief prevalent, especially among the lower class of Germans and Irish, that if the possessor of a chancre copulates with a virgin, or in any other manner is able to infect a perfectly healthy person, he himself will escape further trouble from the disease, and this little patient has probably been the victim of such an outrage. The history of the case is as follows: Alice S——, aged four years, of German extraction, stoutly built, and large for a child of her age. The father and mother positively deny having ever had any venereal trouble; the other children are perfectly healthy, and give no evidence of syphilitic or scrofulous taint. The patient has had scarlet fever and measles. Last summer the mother noticed an eruption on the child's scalp which was found to be eczema capitis; this yielded gradually to treatment and improved slowly, there is, however, a small portion of it still remaining on the right side of the head.

The present trouble dates back to the middle of November, 1890, when the child complained of great pain during urination; to this her mother paid no attention until a few days later, when she noticed while bathing the child that the labia were greatly swollen and inflamed. Not considering this serious enough to consult a physician, she allowed it to run on until an eruption appeared on the neck and about the genitals, which was about one week later; she then consulted a druggist, who unsuccessfully treated the case with a variety of preparations. She came under my observation in my class of diseases of the skin at the North-Eastern Dispensary, on January 6, 1891. Upon examination were found deep and suspicious-looking fissures in the corners of the mouth, two large mucous patches on the lower lip, and an aphthous-like condition of the tongue and inner aspects of the cheeks; also an eruption on the neck, which was at once diagnosed Tinea circinata, but upon closer examination proved to be a much more interesting lesion, as will be seen; immediately beneath the chin and on either side of the neck were found several large, bright-red patches, twelve in number, of circular and oval firmly seated papules covered with exfoliated epidermis, and varying in size from a split pea to a dime; two patches of smaller size situated over the left sterno-mastoid muscle were closely analogous to the eruption of psoriasis. On the back of the neck one patch of the small papular syphiloderm variety was found, another of the same variety over the left jugular vein, and still another over the right sterno-mastoid; these varied in size from a pin-head to a millet seed, their summit being covered with fine scales and being of a dull red or brownish color. On the body could be seen traces of a fading roseola. The genitals were next examined, and there the seat of the trouble was found. Had the child been fourteen years of age or over, my first question would have been "when did you last have sexual intercourse," but considering her age no information could be gathered regarding the attempted copulation.

The labia were inflamed, œdematous, and surrounded with numerous condylomata of all sizes. The vulva was in a filthy condition, due to the constant excretion from the condylomata, which was of a most sickening odor. No laceration was perceptible, a rather wide-spread excoriation at the introitus vaginæ being the only indication of abusive treatment. The hymen was intact and of the annular variety; the perineum was perfect. About the anus were found several condylomata, some being warty in appearance and resembling the syphilis cutanea vegetans; others were of the broad or flat variety, and situated mostly about the nates and vulva; these varied greatly in size, from one-eighth of an inch to one inch in diameter, some having coalesced, forming large patches, and being covered with a grayish, sticky, mucoid secretion.

The condition of the glandular system was most interesting, the epitrochlears were enlarged, that on the right side being scarcely perceptible, while the left was the size of a large pea. The anti-auricular ganglion was much enlarged, while those of the neck generally were less hyperplastic; later on, however, they all become markedly enlarged and typically syphilitic. The axillary glands were enlarged, those on the left side being more pronounced than on the opposite side. The inguinal glands differed to a much greater extent than any of the others, the left being larger than an ordinary sized almond, while the right was not much larger than a pea. There was slight tenderness on pressure of the left inguinal, but even firm pressure on the others caused no pain. The treatment consisted in the administration of Dr. R. W. Taylor's mixed prescription, viz.:

℞. Hydrargyri biniodidi ..... gr. ¼.
Potass. iodidi..... ..... ʒ ij.
Syr. sarsaparilla co..... ʒ ss.
Aquæ ..... ad. ʒ ij.
M. Sig. One drachm every three hours.

Equal parts of bismuth and starch were at first used, dusted on the genitals after they had been thoroughly cleansed. Later on aristol was substituted with very gratifying results. The parts were bathed frequently with a two per cent. carbolic solution, and a pad of absorbent cotton inserted between the labia.

This case is made most interesting from the very youthful age of the child; the probable manner in which the disease was transmitted; the very marked glandular enlargement of the left side as contrasted with that of the opposite side; its rapid improvement under anti-syphilitic treatment; and the combination of the three forms of syphiloderm, viz., 1, the large papular or lenticular; 2, the papulo-squamous, and 3, the small or miliary papular syphiloderm. I have not pronounced this a case of "rape" without careful study and inquiry into all the other modes of infection. Examination has shown all the other members of the family to be free from the disease, consequently towels, wash-rags, knives, forks, pillows, clothing, trousers, bandages, etc., are excluded as being a probable source of infection. One source, however, we are unable to exclude, viz., the water-closet; in this dark, secluded nook many have been made the recipients of gonorrhœa, chancroids, and syphilis, but these are usually from direct infection, and but very few from mediate infection. In this case the excoriations, œdematous and inflamed condition of the vulva, the painful micturition, and numerous condylomata, all point to direct infection in the genitals.

112 East Eighty-first Street.

MEDICAL JURISPRUDENCE.

By HENRY A. RILEY, Esq.,

new york.

There are two matters relating to the prisons which will come before the Legislature which has just begun its session. These are of general importance, though one more particularly concerns this city.

There is little doubt that an effort will be made by some members of the Legislature to repeal the law of 1889, which required work to be done in the State prisons, though under restrictions and limitations which reduced the competition with free labor almost to a minimum. The law of 1888, which it superseded, was an abomination, as it kept the prisoners in idleness, caused great demoralization and ill health among them, and ran up a large bill for the taxpayers to meet.

The labor unions seem in some instances to think that there is still an injurious competition with free labor, but this the most competent observers believe to be a fallacy, and say that, even if it does cause a competition, it is as slight as the difficult nature of the problem will allow. It must be remembered that the subject of prison labor is a very complex one, and cannot be dealt with in any off-hand manner. It deserves, as much as any public matter of general interest, to be discussed without partisan rancor, and to be decided by those fully acquainted with all the necessities of the case. It would

seem wise policy to leave the law unchanged for another year at least, and see how a longer experience tests its merits. This is the view of the Superintendent of Prisons, who says in his report for the year: "The improved condition of the State prisons, as set forth in this statement of the operations and results of the last year, seems to the superintendent to afford the strongest ground for the continuance of the system, without change in any material respect, until a larger experience shall prove that changes will be beneficial, and shall also point out with some distinctness what may be required, if anything."

The other matter relates to this city specially, and is the appointment of matrons at the various police stations to look after the wants of women prisoners, to search them when necessary, and keep them so far as possible apart from the male prisoners. It is amazing that any measure so clearly in aid of decency and humanity should be opposed by a sufficient number of Police Commissioners to secure its defeat. The reason given is that the public do not demand such a change in the management of women prisoners, and also, that it would cause an expense of some $30,000 besides the salaries of the matrons. In regard to the public demand, we believe that the commissioners cannot really believe their statement, for it is probably true that there is not a single proposed change in police methods which has received the strong commendations of all good citizens as this one has. The daily press agree in demanding it, and many humane societies have passed resolutions urging the appointment of the matrons.

A year ago a bill passed the Legislature, requiring the commissioners to appoint matrons, but this was vetoed by Governor Hill on the ground, we understand, that the commissioners would probably act promptly if a bill merely permitting their appointment was passed. Such a measure was passed, and yet the commissioners stand out against every feeling of decency and kindliness. It seems to be the duty of the Legislature to make the appointment compulsory.

In a recent English case an assistant of a chemist, who sold poisons without being registered, was held liable to a fine of £5, although the chemist himself was properly registered and qualified. The court in deciding the case said of the management of drug stores, that it was not intended to force the employment of registered assistants in the ordinary duties of the shop, "but it is otherwise where the assistant is to be intrusted with the sale of such poisons. To leave the selection of such an assistant, without regard to any qualification, to the discretion of his employer, would in our opinion be to defeat the object of the Legislature. One employer in a large way of business might feel that his assistant ought to possess a knowledge of poisons and poisonous drugs equal to his own. Another in a small way of business might be contented to leave the management of his business to an assistant who, though he had knowledge of the general character of poisons, had but imperfect knowledge of their destructive properties and of the various degrees of noxious strength contained in them. A third, who was but seldom asked for poisonous drugs, might think any person of ordinary intelligence sufficient. While a fourth might, without thought of danger, be content to risk a mishap and leave a mere servant in his household, who knew no more than that poison is poison, to represent him.

"In our opinion, the intention of the Legislature was expressly to provide against such a state of things by insisting upon one uniform qualification for every person who should sell, whether on his own account or for any other person, such dangerous commodities, namely registration under the act, based on a certificate of competent skill and knowledge granted after examination by examiners carefully selected and appointed for that purpose. With such a certificate the holder of it may fairly be deemed to possess knowledge, not only of the general effect and operation of the various poisons with which he may be called upon to deal, but what is quite as important, if not more so, for the public safety, knowledge as to the quantities in which each poison may be harmfully or beneficially taken, and the quantities in which, if taken, death or serious mischief would be inevitable."

Some recent decisions may be briefly summarized as follows:

In Georgia the sorrow of a woman over her miscarriage is not a ground for damages.

In Tennessee a man cannot be punished for taking part in a duel on Arkansas soil.

In Kansas, cemeteries do not last forever, but can be abandoned and the land used for other purposes.

In California the Legislature can properly direct that the scholars in the public schools shall be vaccinated.

A Maryland court has declared that no plumber shall practise his profession in Baltimore without a certificate from the Commissioners of Practical Plumbing.

In Massachusetts it is not proper for a Catholic priest to forbid the members of his church to employ a certain physician.

In Indiana mental anguish is a good ground for a verdict for damages for neglect in delivering a telegram.

In Kentucky oral evidence of a dying declaration can be given when a written statement made by the injured man has been destroyed by the accused.

In Massachusetts "Dr. Spencer's Queen of Pain," and "Spinal Paste or Saltrheum Cure," are not valid trade marks; and in Texas "Microbe Killer" is likewise not the exclusive possession of a single manufacturer.

In North Carolina a woman who has had sexual intercourse with a man, but has long since repented, is an "innocent" woman in the eye of the law.

In Illinois a very young child straying into a dangerous place and getting injured can recover damages, the negligence of the parents not being imputed to it.

One of the daily papers says: "An agent of the New Jersey State Board of Health has completed a search for poisonous cosmetics and powders in New Jersey. Thorough examinations were made in Plainfield, New Brunswick, Elizabeth, and Trenton for a brand of face powder of a poisonous nature, which the Board had good reason to believe would be offered for sale in these four cities.

"At only two pharmacies were the prohibited articles found. It is understood that prosecutions will be instituted as soon as the evidence against them can be formulated. Incidental to the examination for the poisonous powders, the fact was discovered that the sale of opium, morphine, and chloral was largely increased during the past year. Several druggists have been notified to stop the illegal sale of these drugs at once, or stand trial."

Undertakers' bills are dangerous things to talk about, it would seem, from a recent trial in this State.

It appears that the undertaker charged $500 for his services during a single day in embalming a body, but on the trial gave no evidence as to the value of his services. The defendant introduced, however, the testimony of six expert witnesses that the services were not worth over $100. The bill was repudiated by the family of the deceased, but was paid by another person.

It was charged against the latter that "no consultation was had with deceased's family to determine as to the justice of the demand, although such consultation could easily have been had, and the injustice of the claim have been made manifest." This charge was held by the court to be libellous.

Professor Lewis A. Sayre has received from London, England, a "Bowman Presentation Portrait," a beautiful mezzotint by I. Cother Webb, Esq., from an oil painting by W. W. Ouless, R.A., which was exhibited at the Royal Academy, 1889. The likeness is a striking one, which Dr. Sayre values highly.

ACUTE ANTERIOR GONORRHŒA: THE INDICATIONS FOR, AND RATIONAL METHODS OF, TREATMENT.[1]

By HENRY S. STARK, A.M., M.D.,

NEW YORK.

WERE it necessary to offer an apology for the selection of this topic, I should present the statement that the treatment of this disease has not received the attention to which its wide-spread importance entitles it; on the contrary, physicians have too often viewed the matter merely in the light of a punishment inflicted by providence on the patient for some infraction of the laws governing our social system. That I am not overdrawing the picture, witness the following quotation, the opening sentences on the treatment of gonorrhœa, by an authority celebrated on two continents. "I do not feel called upon," says he, "to make further suggestions for the benefit of dissolute men who merely desire to continue their irregularities unpunished." This is a good type of a class who consider the treatment a mere triviality. Is it then surprising that gonorrhœa and its sequelæ still remain among the commonest of venereal diseases, or that the amount of contagion afloat should be as great to day as ever before? We of to-day see the dreams of Noeggerath realized in all their appalling significance, we now all but believe that uncured gonorrhœas are the most important factors in the causation of gynecological diseases, and that the physician who treats a urethritis assumes a responsibility that is not to be measured by its comparatively insignificant effects. I have purposely left out of the discussion the consideration of certain well-advertised methods of treatment, because I believe that they who advocate them are actuated by motives other than scientific or humanitarian.

An historical retrospect of gonorrhœa would bring us back to the ancient Jews, Greeks, and Romans; for we gather from our text-books that this disease was known to Moses and Herodotus, the former having had laws enacted for its prevention and spread. Throughout all ages, down to contemporaneous times, the treatment of the disease has been the subject of endless controversy, experiments, and research, and these have produced an amount of literature that is startling in its immensity. It would be amusing, if the scope of this paper permitted, to enumerate the many and ofttimes contradictory methods of treatment that have been the fashion at various periods in the history of gonorrhœa; so that there is hardly a disease in our nosology that has passed through so many phases in treatment; in the matter of drugs it would be easier to enumerate those not used, than to mention the myriads that have been employed. Different methods of treatment have followed each other in such rapid succession that each newly fledged specialist felt it incumbent upon himself to elaborate a theory of his own, or to adhere to one recommended by his teacher. There is thus no universal, systematic method of treatment in vogue, while the duration of an attack is to-day what it was centuries ago. Now, when the duration of a disease whose history is almost as ancient as the human race itself, remains the same to-day as it was when it first became recognized, it is not unfair to assume, without appearing pessimistic, that little progress has been made in its treatment. That the history of gonorrhœa is entirely in consonance with this sentiment is made apparent when we read in our very latest works that, despite the most energetic treatment, the duration of an attack still averages from five to six weeks.

The treatment of this disease, then, is one of the therapeutical problems of the day, yet we may find consolation in the fact that, at no period in modern times did we seem so likely to discover the key to its solution as at present; for if rational inference serves as a means of arriving at therapeutical principles, we may hope that ere long the germ theory of disease will furnish us with an infallible and speedy method, just as it has in other departments of medicine.

The evolution of this biological theory must have convinced older practitioners that they were entirely mis taught in regard to the rational treatment of gonorrhœa; while the discoveries that emanated from its doctrines have accomplished not a little toward establishing genito-urinary pathology on a renovated basis.

The nature of this disease and its virus having been only recently established, any method of treatment is inadequate and unscientific which fails to recognize the fact that, in modern therapeutics the principle of antiseptic medication dominates; for, writing with the conviction that we may expect to cure diseases in proportion as we are able to trace them to their origin, it is not too much to claim that the sooner the treatment of gonorrhœa conforms to the teachings of the Listerian principles, the better for that large and increasing class of persons who are to become the victims of this disease and its sequelæ.

The widely different circumstances under which the disease occurs, both from the physician's and the patient's standpoint, must, of course, be taken into consideration in the treatment. The necessity for concealment in many cases, or inadequate facilities at home, lack of time to carry out topical treatment, or an utter disregard of all directions relating to hygienic or dietetic matters—these are drawbacks which the physician often encounters, and which necessitate a plan of treatment opposed to his best judgment but convenient for the patient, and therefore preferable to him.

The indications for treatment turn upon the nature of gonorrhœal virus and its habitat, the locality of the lesion, the anatomical peculiarities of the urethra, the extent and stage of the inflammatory process, and the variety of diseases to which gonorrhœa belongs. In regard to the nature of the disease, whether we believe in its specific character or not, we must never lose sight of the fact that we are dealing with a suppurating mucous membrane, and the treatment of suppurating surfaces is long established on universally recognized principles. Further, whether we believe or not in an inseparable and constant connection between gonococci and gonorrhœa, the indication, as far as the suppuration is concerned, is again for germicidal medication. Therefore it should be our first and constant endeavor to sterilize or neutralize the virus, then to get rid of the secretions, and to render the urethra an unfavorable soil for the further production of infectious matter.

Although an inseparable etiological relation between the microbe of Neisser and gonorrhœa has not yet been absolutely demonstrated to the satisfaction of bacteriologists in the same sense that certain bacteria of other diseases have, still for clinical and therapeutical purposes it may be assumed to be fairly established. Thus, while there is a clear distinction theoretically between virulent and non-virulent urethritis, or rather specific and non-specific urethritis, there is practically no difference for therapeutical purposes, since the products are nearly always the same, and the same topical treatment is applicable to both; only that in the benign variety the duration of an attack is shorter and the complications hardly ever present.

As to the locality of the lesion, we should bear in mind that the urethral mucous membrane is accessible for manipulation and inspection per endoscope, an instrument too little employed by the general practitioner, but without which accurate localization of urethral lesions is well-nigh impossible. It is also important in this connection to remember that different parts of the urethra may become inflamed at different times, so that the local phenomena of the affection will vary with the seat of the attack, and thus furnish a guide to our therapeusis.

As to the anatomical peculiarities, it is only too well known that the calibre and diameter of the urethra are not constant, but varying, quantities. Further, that the

[1] Read at the meeting of the Metropolitan Medical Society, January 7, 1891.

urethral mucous membrane presents the gaping orifices of numerous mucous glands and follicles, the so-called glands of Littré, which always afford a ready ingress and shelter for gonorrhœal virus. Within these the gonococci and pus-generating cocci may remain stored up, and even hibernate, for a succession of seasons, during which there may be no palpable evidence of disease, unless some indiscretion or excess rekindle the accumulation harbored in the crypts and lacunæ. This is not mere theorization nor exaggeration, for cases of chronic folliculitis, some even leading to ulceration and urinal fistulæ occur commonly enough. Further evidence that the virus may remain latent in these expanded follicular pouches, is the fact that a succession of gonorrhœal attacks will originate at times in an individual who has had intercourse with women who themselves may never have had the disease, a proof that the individual must have supplied the infection from his own urethra. This glandular structure of the urethra plainly demonstrates how necessary direct local treatment becomes, in order to effectually dislodge the virus from its follicular residence; for experience has shown that the virus may at any time find its way out on the surface of the urethra, and reinfect it with the same virulence that characterized a previous attack. It would appear that the constant flushing of the urethra with urine during micturition, or urine charged with anti-blenorrhagics, ought to wash away all microbes, but experience and experiments have demonstrated the contrary. Therefore, I believe that the physician who treats a maiden attack of virulent urethritis only by internal remedies, exposes himself to the charge of unscientific treatment as much as if he were to treat diphtheria solely by the exhibition of internal medicaments. For in this disease it has also been demonstrated that the virus may lurk in some rugæ of the buccal mucous membrane, in the cavity of a tooth, or in some tonsillar crypt, long after the disappearance of the diphtheritic exudation, and that it may creep out at any time, and reassert its virulence.

In regard to the extent of the inflammatory process it is of utmost importance, in order to adopt an intelligent mode of treatment, to know accurately how far along the urethra the gonorrhœa extends. Whether the inflammation is limited to the part of the urethra anterior to the compressor urethræ muscle, or whether it likewise involves the deep urethra, are points about which we must satisfy ourselves before deciding on treatment. For if the urethra behind the "cut off" muscle is affected, it were sheer folly to order injections with an ordinary syringe, since the action of the muscle would shut off all fluids from the diseased surface.

An accurate diagnosis, then, is indispensable to successful results. It would not be within the compass of this article to draw a differential diagnosis between anterior and posterior urethritis, such a description can be found in any systematic treatise on the subject; nevertheless it is important to call attention to this feature, since the treatment in the two varieties is essentially different.

In regard to the variety of diseases to which gonorrhœa belongs, leaving out of consideration the question of its specificity, it is acknowledged to belong to the purely local and infective category. As a local disease limited in its sphere of action, it will require local treatment. For, if it be true that constitutional diseases require constitutional treatment, the corollary follows that local disease requires local treatment. As an infectious disease depending on a specific virus, it would call for some agent destructive to the *materies morbi*.

It is a classical custom among writers to divide the regular course of the disease into three stages, namely, the initial or prodromal, the suppurative or florid, and the declining stage, and to describe the treatment under three corresponding divisions. It must be apparent that such an arbitrary division, which does not depend upon any sharply defined symptom or morbid phenomenon as a basis of demarcation, can never be relied upon as a safe criterion for the selection of individual therapeutical measures. In order to divide the progress of the disease by hard and fast lines into stages, it is better to select some constant and leading feature to serve as a basis of division, and the suppuration being the principle characteristic of the disease, would best, I believe, subserve that purpose. We would then have the course of the disease divided into the ante-blenorrhagic, blenorrhagic, and the post-blenorrhagic stages. This nomenclature I shall employ in this paper. A few words, however, in regard to the prevention and abortion of the disease, before directing attention to the methods of treatment. It is recognized that no person is favored with a complete immunity if he exposes himself to the poison of the disease. That different individuals are differently susceptible to the virus is also known. Thus, it is possible for one or more of a number of males who have had intercourse with the same gonorrhœal subject to escape gonorrhœal infection. This circumstance is explained on the supposition that there are certain conditions of the urethra which favor infection, and others which insure considerably against it. An alkali soil enhances the chances, while an acid soil minimizes them, the bacteria and other organisms thriving better in the former. There are certain special glands scattered throughout the urethral mucous membrane, which in health secrete an alkali fluid to lubricate the canal; this secretion is neutralized or acidified by contact with acid urine; should, however, this secretion at the time of coitus have remained alkali, we have the most favorable pabulum and least resisting medium, in which gonococci develop and even proliferate. One attack of this disease predisposes the individual to subsequent ones; in which respect gonorrhœa does not conform to the prerequisites of the specific diseases, which, having run their course, cannot be made to return in the same subject.

Can the disease be aborted? In other words, are there any methods which may be employed with the view of arresting the progress of the disease directly at the outset? Naturally, we look to those agents which have a strongly germicidal action on the microbes of blenorrhœa and suppuration, the so-called strong antiseptics—bichloride of mercury, carbolic acid, nitrate of silver, peroxide of hydrogen, etc. Now, we know that these cannot be employed to cut short the disease, since they are highly irritant and corrosive, only destroying the germs at the expense of the living tissue which is the seat of them.

For a time injections of a strong aqueous solution of nitrate of silver were the fashion, but thanks to an enlightened pathology of urethral disease, this method has justly fallen into disrepute. To cut short an attack of gonorrhœa at the expense of causing strictures, is hardly an innovation favored by the laity. The feebly and moderately antiseptic drugs, and weak solutions of the strong antiseptics, have all in turn had their day, only to demonstrate their utter uselessness to abort the disease; or else it was demonstrated that urinary concretions follow their employment, which act as mechanical irritants or foreign bodies. To this latter category of antiseptics or abortives belong the zinc, bismuth, and cadmium salts, resorcin, thallin, iodoform, etc. It may, then, be asserted that there is to-day no rational abortive treatment. The ideal of such a method would be furnished by some agent which destroys micro organisms without having a deleterious effect on the living elements which are their seat; or, if we reason by analogy, our hopes and efforts would be directed to those methods of prevention applicable to certain other of the infectious diseases; namely, experimental inoculations with highly attenuated viruses. It is almost utopian to venture such a prediction, yet it is certainly within the range of belief, if this disease depend on a specific virus, as is claimed by those who have made a study of gonorrhœa and its virus. An ordinary observation of every-day events will furnish the most casual doubter with grounds for the belief that, in subcutaneous vaccination preventive medicine finds its most formidable measure of defence against the inroads of the infectious diseases. Fol-

lowing in the wake of the Koch treatment of tuberculosis, and the application of the remedy for the cure of lupus, leprosy, granular lids, cancer, etc., the only wonder is that the remedy has not been employed by genito-urinary surgeons.

Coming now to the methods of treatment, our object in the ante-blenorrhagic stage is not to arrest the progress of the disease, for we have seen that we cannot strangle it, but simply to limit its intensity and to relieve suffering; in other words, the treatment is palliative, and is essentially the same as in the early period of most acute local inflammations, with the exception that the temperature and other symptoms of a febrile movement are never so marked as to call for antipyretic measures. The general principles which govern the treatment are those of a prophylactic, hygienic, and dietetic nature. In regard to these all authorities are in perfect accord, and they are familiar to all. Of drugs, there are none known to exert a specific curative influence. The only drug really indicated, unless the constitutional disturbances are so prominent as to call for interference, is an alkali exhibited directly after meals, to neutralize the urine. This latter method of administering the drug is imperative, since, if the alkali be given on an empty stomach, in the absence of the gastric juice, the likelihood is that it will be quickly diffused into the blood in its alkaline state, where, meeting with the neutral phosphate of soda, it will, by a crossed chemical reaction, be converted into an acid phosphate of sodium, which thus increases the acidity of the urine, the very object we are aiming to avoid. This feature, in the period of administration of an alkaline salt for purposes of rendering urine alkaline, must be kept in mind.

Local interference in the ante-blenorrhagic stage is contra-indicated even if the patient be seen early enough. The employment of the so-called antiblenorrhagics, the balsams and ethereal oils, is also to be avoided, as there is as yet no blenorrhœa. This stage ought not to be treated energetically nor heroically. Fortunately for some patients, they do not present themselves for treatment during this stage, either because the symptoms are too slight to attract their attention, or if they understand them, they feed on the hope that the disease will terminate spontaneously and without treatment. I say fortunately, for there are too many physicians whose routine treatment of this disease, in any or all of its stages, is without any deviation, the ordering of copaiba internally and astringent injections locally. Is it then to be wondered at that the treatment of gonorrhœa has fallen into other hands than those of reputable physicians; *e.g.*, medical charlatans, druggists, drug-clerks, irregular practitioners, commercial travellers in whom the disease is endemic, and some "good friend."

It is in the second, or blenorrhagic, stage that active measures are indicated. Now judgment and skill are called into requisition. This stage has always been the bone of contention, the question of injections or no injections being the much-mooted issue. Until within a few years ago, authorities were about equally divided in the matter; to-day, through the light of antiseptic surgery, the pendulum is swinging on the side of those who advocate local treatment directly the suppuration begins. It used to be taught that injections were often the cause of later strictures and of certain complications, but time and experience have, I believe, demonstrated the fallacy of this supposition, and have proven the converse proposition, that the complications and sequelæ are more liable to follow when local treatment is omitted. That the use of injections has been abused, by emanating from men who did not understand the nature of the disease, and who could not gauge its intensity, goes without saying, nor will I deny that harm has often resulted from their indiscriminate employment; but I think it could be proven that, in those cases of gonorrhœa where complications followed the use of injections, the trouble lay not in the method of procedure *per se*, but rather that the injection was ordered prematurely, or too strong solutions were employed, or else that the patient was not properly taught in the *technique*. What I claim is that, if weak injections be ordered and the patient be instructed exactly how and how often to inject, no harm can follow their employment in the blenorrhagic stage of uncomplicated acute anterior urethritis. The strength of the solution should be inversely in proportion to the amount of discharge, that is to say, the more profuse the suppuration the weaker the solution; every detail of the slight operation ought to be reviewed, and we ought to be certain that no complication be present when ordering the injection. The advantages of direct topical treatment over all other methods is a strong argument in its favor. By this method alone can cleanliness be observed, the cardinal virtue in the treatment of suppurating surfaces, and by this method alone do we effectually drain the urethra of its secretions.

There is a great deal of truth in the old surgical motto, "*ubi pus, ibi evacua*." Wherever there is pus, get rid of it. What more effective manner than by the systematic irrigation of the urethra, could be employed in the treatment of gonorrhœa, I fail to understand; and at the same time, remembering how easily the virus may insinuate itself in some recess or reduplication of the urethral mucous membrane, I fail to understand how anyone can hesitate to avail himself of this therapeutical resource.

Nothing in what has preceded should be so construed as to lead you to believe that the method by injections is the only method to be followed in the blenorrhagic stage. On the contrary, I believe in the superior efficacy of combining several therapeutical measures, and thus charging the disease from several channels. The administration of the so-called antiblenorrhagics—cubebs, copaiba, sandal-wood, etc.—is to be recommended in conjunction with topical treatment. The value of these drugs in blenorrhagic processes has long ago been proven. There is abundant experimental and clinical evidence in favor of their usage. It has been shown satisfactorily that they exert a selective influence on the mucous membrane of the genito-urinary tract, where they act, when suspended in the urine, by sterilizing the secretions and thus depriving them of their noxious influence. Oppenheimer, after a large number of experiments to test the antiseptic power of copaiba, found that if the drug was applied directly to the micro-organisms, its effect was slight, but that urine charged with copaiba was a poison to bacteria. Ricord treated a number of gonorrhœa patients, who were also suffering from urethral fistulæ, with copaiba internally. The result was, in these cases, that the urethra behind the fistulæ, which was washed by the urine, recovered, while the part of the urethra in front of the fistulæ remained diseased, and continued to suppurate until injections of the patient's urine were made into it. The oft-times bad effects of the balsams and ethereal oils, however wisely administered, have limited their employment to a considerable extent, so that to-day many physicians have discarded them entirely from their pharmacology, with equally good results. Many experienced and knowing patients often request their medical advisers not to prescribe these drugs, stating that between the two evils of having gonorrhœa and having to take copaiba, they would much prefer the former. I always concur in their appeal. I often wonder how those physicians who are constantly condemning the use of injections for fear of injuring the urethra and thus opening new portals for infection, reconcile their apparent inconsistency in not hesitating to apply harsh topical treatment to catarrhal affections of other mucous membranes, some more delicate than the urethra, as the eye, ear, mouth, and nose. Some of these physicians do not stop to invade, and with perfect immunity, even serous cavities, as the peritoneal and pleural, during an acute grade of inflammation, with all manners and sorts of instruments. Somehow, their dread of injuring these membranes is a mere bagatelle, but the slight touch of the smooth surface of a syringe against the urethra sets their imagination aglow with

pictures of all the pathological lesions that the human urethra is heir to.

Presuming the disease to have passed into the post-blenorrhagic stage, the painful micturition having ceased, and the suppuration having almost entirely stopped, or been replaced by a thin watery discharge, the same treatment as in the blenorrhagic stage is to be continued, except that stronger injections may be ordered. Should there be left over, after the acute inflammatory process has abated, a slight watery discharge, as evidenced by finding the lips of the urethra glued together on waking in the morning, it should be interpreted as a slight irritation of the urethral membrane, or as a lack of tone in its capillaries or in the entire system. An attempt should then be made to alter the action of the blood-vessels of the urethra, so that they may gradually be brought to secrete again the healthy mucous fluid with which the canal is naturally lubricated. For this purpose the introduction of a large-sized sound once a week, preceding the operation by a copious irrigation of the anterior urethra with a very weak and warm solution of permanganate of potash, answers perfectly well. The passage of the sound possesses the additional advantage of dilating any inflammatory stenosis that may be present and might prove the starting-point of an organic stricture.

It is in this stage of the disease that the important question will come up, when may we consider the patient cured, and what is the criterion of cure? The patient will consider himself cured when the discharge and the *ardor urinæ* have ceased, but the physician should require more assuring evidence than the absence of these subjective symptoms. Often the physician coincides with the patient's view, without satisfying himself to the contrary, with the inevitable result that the attack recurs after an apparent cure. I venture to assert that many a case of chronic urethritis, granular urethritis, posterior urethritis, organic stricture, etc., can be traced to the fact that patients were prematurely discharged as cured, or to the fact that when such patients suggested a cessation of treatment and a return to their former habits of life, they were not sufficiently impressed by their physician of their folly, or else the physician submitted to the appeal of his patient without a comment.

To-day, such *prima facie* evidence as cessation of the blenorrhœa and *ardor urinæ* is no longer decisive. It would appear that the ideal test would be the continual absence of gonococci and pus-cells, but this method is impracticable for general office-work. Therefore, the clinical test of examining the urine of clap patients for the so-called clap-threads or flakes and for pus, answers all our purposes. Their continual absence for about ten to fourteen days would indicate a cessation of all treatment, and a gradual return of the patient to his former *régime*.

270 Seventh Street.

THE BACILLI IN THE TALMUD.

By NAPHTALI HERZ IMBER,

NEW YORK.

Last year, while the influenza was causing such havoc on the Continent, I published an article in the *Jewish Standard*, of London, on "The Influenza in the Talmud," in which I showed that the "sneezing visitor" had often knocked at the talmudical gate, and that the sages of the Talmud knew all about his habits and how to meet his invasion; for they had traced his footprints ever since his first appearance in the time of the Patriarch Jacob. Now that the world is stirred by the discovery of the infamous bacillus of Koch, I will lay before the readers of the Medical Record some facts about it which the sages of the Talmud brought to light nearly two thousand years ago. The origin of all known and unknown diseases is, according to the Talmud, to be referred to a cold or chill. "Air" plays an important rôle in the world of misery. The air, says the Talmud, gives birth to numbers of creeping things, just as does the Mother Earth. On the windy wings of the air the trio—plague, cholera, and influenza—are flying from east to west, from north to south, throwing into our world their poisoned arrows of destruction. The invisible legions at their command put it in their power to attack the human being in his own home—his body. In the air, says the Talmud, is living and moving a numberless throng of invisible insects which are constantly threatening our lives, and if it were allowed our eyes to behold these hordes of "mazikim" (this is the talmudical term for bacilli, and means literally "dangerous ones"), no living beings could stand them. In another part the Talmud poetically calls them "sheidim" (invisible demons, robbers, or breast-dwellers, as they like to take up their abode in this region).

These "dangerous ones" are grouped by the Talmud into four classes, as follows: 1. Kinim, an invisible insect which takes up its abode in the abdomen, attacking either man or the lower animals, indifferently. 2. Zolooim, a sort of worm. 3. Murna, a sort of trichina; and 4. Kordakus, a word meaning invisible demon. The bacilli of the first group are not regarded as dangerous, and the Talmud jocularly remarks that a good morning meal will drive them out from the abdomen. More dangerous are the insects of the second class, the Zolooim, which not only invade our bodies, consumption and leprosy being due to their action (under the skin of a leper, says the Talmud, nestles a sort of worm), but they also make their way into stone and wood, and like to dwell in dirty clothes. (House- and clothes-leprosy is well-known to readers of the Bible.) It is curious to note that popular belief among all peoples ascribes bodily pain to the action of a certain worm, the toothache worm being perhaps the most familiar example. In the third class we find the Murna, or trichina, which is said to infest the lungs of men and animals. Finally we have the Kordakus, or Shed (invisible demon)—bacilli which dwell by preference in fluids such as water or wine. Unclean portions of the body of man, an unclean house, or dirty clothes, are especially liable to become infested with the invisible visitors of the second or third class, and the consequence of such an invasion is the appearance of consumption or leprosy. We find therefore that the laws relating to cleanliness are very numerous. The first duty of a Jewish housewife is, according to the Talmud, to keep the house clean. "Keep the air clean" is a talmudical rule. In a place where there is the dead body of a man or animal the surrounding air is declared to be unclean. This unclean area extends for a distance of four cubits on all sides of the corpse, and if a person finds himself within this circle of "unclean air" he becomes himself unclean (even though he may not have touched the dead body), and must wash according to the mode prescribed by law before he can be declared clean again.

In the Mosaic time the nature of leprosy was as a sealed book, and the leper was sentenced by the ignorant priests to be forever an outcast from among men; but in the talmudical time the rabbis (not the priests) cured the leper by performing upon him an operation whereby the bacilli, hidden beneath his skin, were destroyed. The Talmud remarks upon the fact that there are no lepers in Babylon, and says that it is because the Babylonians are continually washing themselves in the Euphrates River, and drink much beer. A propos of this, there was an article in the London *Daily News* last year, concerning a woman who had been relieved of her leprosy, after the physicians had failed to cure her, by drinking large quantities of beer. The Jewish laws in regard to cleanliness were all framed with the design of preventing the invasion of bacilli within the domestic circle. All kitchen utensils and other things which have become unclean by contact with the flesh of certain unclean animals must, in order to destroy the bacilli, be cleansed—iron by fire, glass by water, while earthenware pots should be destroyed. It is forbidden to drink water which has been standing for several hours

in an open glass or other vessel, for it may then become the medium for the dissemination of the fourth group of bacilli, the "fluid dwellers." Before and after eating it is commanded that the hands be cleaned with water. Certain animals and various creeping things, on land and in water, which are liable to be infested with bacilli, it is forbidden men to eat. The meat of an animal which is to appear upon a Jewish table must first undergo an examination. The manner of killing an animal is not determined by law; the animal may be killed with a stone, and anyone may do it, says the Talmud; but the point upon which the law is strict is the "Bedika," or investigation, and this can be done only by men who have been specially trained for that purpose. The "Bedika" is a very hard task, for after the animal is killed the lungs and other parts must be carefully examined to see if they are free from "Murna" or the trichina bacillus. The presence of small black spots in and around the lungs marks the existence of these bacilli. If the lungs are in a healthy condition, the meat is declared "kosher" (right, fit for food), and if they are not, it is "treipha" (spoiled, not to be eaten). The meat obtained from the butcher must, when brought home, undergo a purification by means of salt and water for the space of an hour, in order to destroy any bacilli that may have gained access to it. Animals are the medium through which bacilli are smuggled into the body of man, and for this reason the Talmud forbids one to sell, even to a Gentile, treipha meat instead of kosher, unless it be upon the latter's special request. All our laws are based upon sanitary principles, and they were given, says the Talmud, for the sake of life, and not for death. It is the law which has freed our race from leprosy, and it is the law which prevented the demon bacilli from entering the Jewish home, to destroy the domestic peace by bringing consumption. But since we have begun to neglect the law regarding food, bacilli have broken through the guarding line, and many a Jewish home has been invaded by consumption, although the number of sufferers of our race is as yet very small in comparison with those of the Gentiles.

The Lymph as Described in the Talmud.—The lymph, as prepared by Professor Koch, consists of the substance of the bacilli extracted by glycerine. Did the talmudic lymph consist of the same material? To this question we must answer a probable yes. But before describing the ancient lymph, I desire to say a few words about scientific development among the sages of the Talmud.

When the priests controlled Judaism science could not advance, for it was restrained by the operation of certain laws. For example, medical science is based upon the teachings of anatomy, but the priests were forbidden by law to deal with dead bodies. Ignorant as they were of the composition and formation of the body, medical science was to them a sealed book, and never could they cure a leper or a man stricken with other disease. They could prevent the spread of an epidemic, but to cure they were unable. Upon the return from the exile the rabbis became the leaders of the nation, and under their rule the evolution of science took place. The sages of the Talmud paid attention to anatomy, and long before Æsculapius laid the corner-stone of the medical structure, the scientific building of the Talmud was complete from top to bottom. In the college of Rabbi Ismael the knife of science was applied to the corpse of a woman (who had been put to death by the Romans) for scientific and anatomical purposes, to demonstrate to the pupils the veins and nerves of the human body, and to familiarize them with the workings of nature within the secret chambers of life. Under the rule of the priests the leper was condemned to be the outcast of society, but the medical rabbis cured him by an operation whereby the hiding place of the Zolooim (bacilli of the second class) was exposed, and the invisible enemies destroyed, the leper being thus restored to society. The wonderful operations which they performed for the relief of cancer, consumption, and leprosy show us how advanced they were as regards medical science. Our moderns would be struck with astonishment were they to read the little tractate entitled "Cholet" (tents), a booklet dealing chiefly with anatomy, or "Negoim" (leprosy). It is greatly to be regretted that many of the tractates which deal especially with the various diseases and their treatment have been lost in consequence of our wanderings for two thousand years, and of our persecutions during the exile. Perhaps they are still hidden on the dusty shelves of the Vatican or elsewhere. But still I can gather, from many sentences scattered through this vast book, or books, of the Talmud much information concerning the talmudic lymph.

There is a talmudic medical rule to the effect that, in the source of every disease there is to be found the means of healing. On this principle the Talmud orders that old wine be given to one who has a fever, for the heat produced by the wine will drive out the heat of the fever; and for the same reason it prescribes the oil of a scorpion to heal the sting of this insect. To this day the Orientals employ this mode of treatment with success, and when one of them has a fever they put hot bricks under his arms so that the heat of the bricks may drive out that of the fever. The above-mentioned principle is the first rule in the medical part of the Talmud.

Now, as to the composition of the lymph referred to. The Talmud says that if Kordakus (the bacillus of the fourth group, whose natural abode is a fluid like water or wine) enters the body of a person, the latter shall have an injection of a certain fluid through the nostrils, saying at the same time, "I am tasting the water which is thy blood" (that is the blood of the bacillus Kordakus), "and which will kill thee." It must be remembered that the fluid bacilli of the fourth group are those which cause consumption and cancer. Must not the composition of the talmudic lymph have been the same as that of Dr. Koch?

Let us remember that the idea of experimenting with a lymph is a modern one, and that it is described in modern phrases; yet the voice is but a voice from the grave, the voice of the Talmud buried in the grave of ages two thousand years deep.

Clinical Department.

FRACTURE OF THE NECK OF THE FEMUR IN A CHILD.[1]

By ROYAL WHITMAN, M.D., M.R.C.S.,

ASSISTANT SURGEON TO OUT-PATIENTS, HOSPITAL FOR RUPTURED AND CRIPPLED, NEW YORK.

On April 9, 1890, the patient, a boy, aged eight, fell from a fence into an area, a distance of about eighteen feet, striking upon his right side. After the accident he was unable to stand, his head and body were severely bruised, and his right knee swollen and painful. He was put to bed, and three days later a physician was called, who, according to the mother's statement, directed his attention exclusively to the knee, and after four weeks, the swelling having subsided, pronounced him well; but as the pain in the knee still continued, and as the child showed no inclination to walk, another physician was consulted, who said the case was incurable, and refused to treat it. He was then taken to a general hospital, and from there referred to the Hospital for Ruptured and Crippled, where he was brought on May 21st, six weeks after the injury. When he was placed upon the table it was noted that the foot was markedly everted; the knee appeared perfectly normal. On examination of the hip it was found that motion, though somewhat painful, was but slightly limited. Extension was perfect, flexion to ninety degrees. Abduction and adduction, though somewhat resisted, nearly normal, but inward rotation of the

[1] Case presented to the Orthopedic Section, New York Academy of Medicine, December 19, 1890.

everted foot was considerably restricted. The right leg half an inch shorter than its fellow, the shortening being due to an elevation of the trochanter above Nelaton's line, and a corresponding loss in the base of Bryant's triangle; the trochanter was broadened, somewhat sensitive to pressure, and beside its elevation was approximated three-quarters of an inch to the middle line of the body. There was marked atrophy in the gluteal region and thigh. A diagnosis of fracture of the neck of the femur was made, a long traction hip-splint with high shoe applied, and in a few days the boy was walking about, free from pain and discomfort. The apparatus was removed at the end of four months, the appearances and measurements being then, practically, as have been described. Although there is now no pain, and almost no limitation of motion, the boy still walks with quite a marked limp.

Thus, to recapitulate, we have a severe injury, resulting in an immediate inability to use the limb, which now, six months after the accident, shows a shortening of half an inch, an elevation of the trochanter and its approximation to the middle line, while the movements of the joint are free, painless, and practically unimpaired. With this evidence I think we are justified in making a diagnosis of extra-capsular fracture, probably impacted. This injury is excessively rare in childhood, and in the literature of the subject I am able to find but one similar case, that in a youth of sixteen.

Aside from its infrequency there are, I think, one or two points of interest in the case. 1. As to treatment. The brace which was so efficacious in this instance might, it seems to me, be used as an after-treatment for similar injuries, which are so often tedious and intractable in adults. Possibly if the joints were protected by such an appliance the pain, which often lasts for years after the accident, might be avoided, and a better functional result obtained. 2. It shows the importance of an accurate history, without which, in this case, the pain in the knee, the atrophy, the shortening, with the thickened and sensitive trochanter might have been mistaken for hip disease.

APPENDICITIS — DEATH IN FORTY-TWO HOURS.

By JOSEPH N STUDY, M.D.,

CAMBRIDGE CITY, IND.

The following case seems of sufficient importance to be placed upon record. On Tuesday night, January 2, 1889, at nine o'clock, I saw, in consultation with Doctor S——, the Rev. Mr. S——, aged twenty-six, American, and whose previous general health had been excellent. In the fall preceding he had an attack of severe pain in his bowels, which after a few hours yielded to anodyne medicines. On the morning of January 1st the patient, in company with his father, arose early in the morning, and without eating breakfast walked one mile and a half to the railroad station, where they took a train at 6 o'clock for a neighboring town, sixteen miles distant. During the morning he did considerable walking and ate some apples, and at ten o'clock he took the train home, walking to his house from the station. At dinner-time he said he was suffering pain in his bowels, and during the afternoon anodyne medicines were given to him, with apparently but little effect. Later in the afternoon Doctor S—— was called to see him, and morphine in frequently repeated doses was given hypodermically to relieve his suffering. At the time of my visit the man's countenance betrayed great anxiety and suffering. He was lying with his thighs partially flexed, the soles of his feet resting upon the mattress; the abdomen was distended and extremely painful on being touched; his pulse was so rapid that it could not be accurately counted; his temperature was about normal (at no time had there been any increase of temperature), and the respirations were increased and thoracic in character. There had been little or no vomiting, and the bowels had, prior to this attack, been active. The man's condition continued much the same until his death, which occurred at six o'clock on the following morning, forty-two hours from the first complaint of pain. The autopsy revealed a general peritonitis. The abdominal cavity contained a large quantity of pus, the intestines were matted together with fibrous adhesions, the cæcum was comparatively empty and contained some pieces of undigested apple incorporated in a mass of mucus. In the walls of the appendix, near the opening from the cæcum, were two perforations; the walls of the cæcum and appendix were greatly thickened, as was also the surrounding connective tissue. Death from inflammation about the head of the colon may occur with little or entire absence of fever; but this is the exception, not the rule, and it would seem almost incredible that an inflammation so extensive as in this case could occur without fever. Inflammation occurring about the cæcum or appendix usually pursues a course varying from a few days to several days, and death resulting within such a short period from the time of attack I believe to be uncommon. The query might be propounded, Was not the previous attack of pain most likely an inflammation resulting in resolution, and might not the eating of the raw apples upon an empty stomach, and a partially empty intestinal tract, have acted as an exciting cause in producing this inflammation, so rapid in its course and terminating so disastrously?

A CASE OF HEMORRHAGE INTO AND AROUND THE BRONCHIAL GLANDS.

By HENRY A. GRIFFIN, M.D.,

HOUSE PHYSICIAN TO THE NEW YORK HOSPITAL.

Bleedings of various sizes and from various causes into the cellular tissues of the mediastina are not of extreme rarity; but hemorrhage of the peculiar character and location as described in the case reported appears, so far as I am able to discover, extremely uncommon. Not only from a pathological stand point does the case have some interest, but particularly from the clinical side, since the symptoms all pointed strongly to hemorrhage of considerable size, whereas the autopsy showed that not more than three or four ounces had been lost. That the condition is not one of practical importance, since it cannot be diagnosticated or treated, is undoubtedly true; but from its vagueness and the unsatisfactory nature of all explanations concerning it, the case appears to me to offer features of interest.

What was its etiology and pathology? What gave rise to the symptoms of large hemorrhage? What was the immediate cause of death? Because of the unanswered (satisfactorily) condition of these questions I desire to report the case.

P. L——, aged twenty-eight, born in Ireland, single, and a longshoreman, was admitted to the medical division of the New York Hospital on August 11, 1890, and gave the following brief history: Previous health good. Present illness of five days' duration, only symptom complained of being cough, with slight mucous expectoration; moderate malaise and prostration; slight febrile sensations, and a sharp pain at the base of the right chest, behind and at the side. On admission the temperature was 101° F.; respirations, 32; pulse, 108. Physical examination showed a few moist bronchial râles evenly distributed over both lungs; slight diminution of voice and respiratory sounds over the bases of both lungs behind; over the right base, behind, a moderate amount of dulness, of limited extent, and a few fine pleuritic râles. Moderate pharyngitis. Pulse rapid, feeble, and somewhat irregular. Tongue pale and coated. Patient anæmic and considerably prostrated.

Milk diet was ordered, and patient was placed on whiskey and fluid extract of digitalis in moderate quantities.

Following admission he became much more comfortable, his pulse improved, and his cough was less troublesome. He breathed easily. During the early evening he rested comfortably, but did not sleep. At 11 P.M. I was called to the ward by a report of his apparently serious condition.

I found him in a state of extreme restlessness, tossing from side to side. His extremities were cold and his radial pulse very faint. He complained of feeling chilly, and at the same time was very thirsty. He had a dyspnœa so extreme as to amount to "air hunger." The nurse reported that he had vomited once. These symptoms were so suggestive of loss of blood that I seriously entertained the possibility of the patient's having had typhoid fever with a complicating hemorrhage. Energetic stimulation, together with the administration of morphine was at once employed, but the patient sank rapidly and at 11.30 he died. One general convulsion immediately preceded death. The post-mortem temperature was 102° F.

The autopsy, made August 12th, showed the tissues of the anterior mediastinum to be œdematous and infiltrated with clear serum. The left lung was everywhere adherent to the chest-wall by loose connective-tissue adhesions, in the meshes of which was contained clear serum. The right pleural cavity contained 1,700 c.c. of clear serum. There was intense congestion of the trachea at its bifurcation. One bronchial gland of the right side was enlarged and caseous, and surrounded by a coagulum of blood in size equal to that of an English walnut.

The pre-tracheal glands were markedly enlarged, necrotic in places, and the seat of numerous hemorrhages, which also involved the surrounding tissues. All the other organs were practically normal. The whole amount of blood lost was about three ounces.

Progress of Medical Science.

The Proteids Found in the Urine in Albuminuria.—The following is a summary of the views of Dr. Paton on this subject: 1. Senator was right in his conclusion that, in all cases of albuminuria, both of the chief proteids of the blood plasma are present. 2. The proportions of serum albumin and serum globulin may vary within wide limits, the quotient of the amount of serum-globulin being sometimes as low as 0.6, sometimes as high even as 39. 3. In acute nephritis, when blood is absent the quotient is high; when hæmoglobin is present the globulin is, of course, in excess. 4. As the disease becomes more chronic, the quotient sinks, and in the terminal stages of the disease may fall as low as 0.6. This alteration depends upon the condition of the patient rather than upon the state of the kidney, and is probably related to a similar change in the blood plasma. 5. Amyloid disease cannot be distinguished from the ordinary forms of chronic nephritis by the high proportion of serum globulin, as was formerly maintained by Senator. 6. Maguire's suggestion that functional albuminuria is characterized by the high proportion of serum globulin is not correct. 7. In every case the proportion of the proteids to one another varies much in the course of the day, and, in comparing the proportion of these proteids in different cases, it is necessary to examine specimens of the mixed urine of the twenty four hours, and to take into account the nature of the diet. 8. The proportion of serum globulin is always highest during the night. It falls greatly after breakfast, when it reaches its lowest point in the twenty-four hours. In most cases it again rises in the evening. The precise connection of the alteration in this proportion with the taking of food cannot be considered as definitely settled. 9. Milk diet, as observed by Lecorché and Telamon, has a peculiar effect in increasing the proportion of serum-albumin. 10. The amount of proteids passed appears to bear a tolerably direct proportion to the amount of proteids taken, and, excluding milk diet, the increase of the proteids in the urine on a rich diet in these substances appears to be chiefly due to an increase in the serum albumin. 11. The variation in the proportion of the albumin to the globulin in the urine is frequently so great that we can hardly believe that it is connected with a similar change in the plasma. The few experiments we have performed would suggest that a high pressure favors the transudation of serum-albumin, while a low pressure increases the proportion of globulin transuded.—*British Medical Journal.*

Separation of the Funis from the Child during Parturition.—Dr. James Ferguson gives an account of this rare case in the *British Medical Journal*: On November 26th he attended Mrs. L—— in her sixth confinement. Nothing unusual occurred to distinguish the case from an easy labor till the head came almost to the perineum, when, through several successive strong pains, it assumed a stationary position, neither advancing nor receding. This ended, however, by a strong uterine contraction suddenly propelling the head through the outlet. Again, with the head born and the neck grasped in the vulva, there was another period of immobility on the child's part through two full and firm pains. The skin was livid, but no attempt at respiration occurred. He was just introducing his finger with the object of disengaging the shoulders from the maternal parts when, by another powerful pain, the birth was suddenly completed. On turning the child round, he was struck to find no umbilical cord attached, while dark venous blood was oozing freely from the navel. No sign of life remained, and a slight effort to induce respiration only caused increased hemorrhage. The loose end of the funis was found presenting at the vulva. The cord turned out to be of average length and circumference, save that the last two inches abruptly doubled in thickness, and this portion was of a gristly consistency, and could scarcely be bent to any degree. The broken surface appeared of the same hard structure throughout. The separation from the child took place exactly at the junction with the skin, and could not have been more neatly effected by a dissecting scalpel. The child was a particularly well-developed male, with no indication of death predating the labor.

The cause of the two pauses in the child's descent, and of the sudden propulsion following, was, no doubt, due to the rigid condition of the bit of cord in the first place, and to sudden fracture and separation, perhaps in two stages, in the second. As to the actual condition of the thickened portion, he could only detect—the examination being hurried and superficial, however—an apparently cartilaginous structure, and no calcareous deposit. The case was not only unique in his experience, but he can find no similar instance recorded in any work of reference within reach.

Hæmoptysis in Apparently Healthy Persons.—Hæmoptysis is a symptom which has always a serious aspect about it, causing both physician and patient to be apprehensive of impending pulmonary tuberculosis; but that too much significance should not be assigned to it *per se*, is shown by the report of some cases published by Dr. Newman. In the first case a man, aged forty-nine, complained of frequent attacks of hæmoptysis, the amount of blood lost varying from a few drops to an ounce and a half. Despite the attention of many practitioners from time to time, the attacks continued, and had lasted for sixteen months before he came under the care of the author. No physical signs were discoverable in the chest, and the patient's health was good. Inspection of the larynx and trachea, the latter being visible as far as the bifurcation, failed to show at the first three examinations any morbid condition. At the fourth examination the larynx and trachea were observed to be tinged with blood; and after the patient had cleared the air-passages as well as possible by coughing, a small bleeding point was noticed immediately below the anterior commissure. The

blood oozed from it slowly and trickled down the trachea. With local treatment the hemorrhage ceased and complete recovery followed. In another case the hæmoptysis had continued for nine months, the patient being a man aged fifty six; the amount of blood lost varied between an ounce and an ounce and a half, and the attacks usually occurred once a month. No physical signs of phthisis could be detected in the chest. After, however, a large hemorrhage, the naso-pharynx, pharynx, larynx, and trachea were carefully examined. The two latter were deeply blood-stained as far as could be seen, but no bleeding point could be discovered; but two days afterward a little erosion was observable on the anterior aspect of the trachea, just below the cricoid cartilage, and the surrounding mucous membrane was moderately injected. Two days subsequently to this the lesion just described had completely disappeared. Twenty-six days later the hemorrhage recurred, and the lesion referred to was observed for a second time. Local treatment was persisted in for six weeks, and a complete cure was accomplished. In a third case the hemorrhages were more serious. On one occasion a pint of blood was lost. After one severe hemorrhage an examination was made by the author. The pharynx and soft palate were swollen and relaxed, and the vault of the pharynx was very shallow from before backward. On the upper and back part of the pharyngeal arch a number of distended veins were discovered. At the beginning of the examination these varicose veins were intact, but fron the irritation produced by instruments, bleeding was induced which continued till the next day. The first treatment adopted was the employment of solid chromic acid to the distended veins. This failed, however, to effect any improvement, and a few days afterward electrolysis was employed, the positive pole being applied to the pharynx, and the negative to the neck. This treatment was adopted on three occasions, with the interval of a week intervening. Ultimately the veins were completely occluded, and three years later the patient had never had any return of the hemorrhage.—*Medical Press.*

Physical and Chemical Changes in the Blood in Disease.—Dr. Sciolla, of Genoa, at the recent Congress of the Italian Society of Internal Medicine, reported some interesting experimental researches on physico-chemical changes of the blood in different morbid conditions. He stated that the density of the blood diminishes during acute febrile states, and the first stage of convalescence, increasing afterward with greater or less rapidity according to the nature of the disease. The same thing is always observable in the density of blood-serum, with this difference, that it begins to increase as soon as there is any improvement in the condition of the patient, sometimes, indeed, a short time previously. The density of the serum is increased in malaria, while that of the blood is diminished. Tuberculous affections, unaccompanied by serious alterations of the blood, only slightly modify the density of blood-serum and blood. The densities of blood-serum and blood are both diminished in catarrhal jaundice, probably owing to defective assimilation of food. The density of the blood is almost normal, while that of the serum is increased, in cirrhosis of the liver, and in cancer of the gall-bladder. The densities of blood and serum are not sensibly diminished in benign forms of diabetes. The greatest diminution in the density of the blood is observable in diseases accompanied by grave morbid changes of the blood. The most striking examples were those seen in three fatal cases of pneumonia. Dr. Sciolla also observed the chemical modifications of the blood in pneumonia, typhoid fever, malaria, anæmia, and in leucæmia. About the fourth or fifth day of croupous pneumonia there is a marked diminution in the albuminoid substances of the blood, especially the globulin. The extractive matters increase during the febrile period. In convalescence the quantity of albuminoids, especially of the globulin, and also that of the serin, increase. The dry residue of the blood is not much diminished during the first stage of the disease, but it is so during the second stage, and continues less until convalescence. In typhoid fever the albumins of the blood diminish progressively (unless the diarrhœa is excessive), and this diminution occurs at the expense of the serin. The extractive matters gradually diminish during the whole of the febrile period, and even during the early stage of convalescence. In malarial fevers the amount of the albuminoids in the blood serum (especially the serin, and in a less degree the globulin) and the dry residue of the blood diminish rapidly, while the dry residue of the serum and the extractive matters of the serum increase with the duration of the fever, the former in a slight degree, the latter enormously. In chloro-anæmia the albumins of the serum (especially the globulin) and the dry residue of the blood diminish, while the dry residue of the serum increases. In leucæmia the amount of dry residue of the serum is very high, and the albuminoids of the serum are also above the normal, the serin being especially increased.—*The Lancet.*

The Local Treatment of Enlarged Spleen.—Mosler contributes an article on this subject. He commences by drawing attention to the dangers of operative interference in cases of enlarged spleen, and states as the results of his experience that the hemorrhagic diathesis is often associated with an enlarged spleen, which naturally renders the operation of extraction an exceedingly dangerous one, and what adds considerably to the risk is that the tendency to hemorrhage often remains latent in such cases (*The Lancet*). In addition to this danger, there is another more probable and serious one—namely, that the lymphatic glands on other parts of the body may already be affected, in which case splenotomy may only hasten the general disease. Mosler, has, therefore, for some time tried other local remedies rather than extirpation. He first used parenchymatous injections of a two per cent. solution of carbolic acid, and later injections of Fowler's solution. With the latter he obtained good results in a patient with an enlarged spleen, the result of malarial fever. Mosler also employed Hamond's method of injection of ergot, and also Jager's processes—simple puncture, electro-puncture, and injections of sclerotic acid. In Jager's case death followed a few hours after the injections of the sclerotic acid. In spite of fourteen punctures and four electro-punctures, no trace of hemorrhage was found in the parenchyma of the spleen. One fatal case which Mosler had, caused him to frame the following rules for the injection of drugs: 1. Only enlarged spleens of firm consistence are suitable, provided these are not accompanied by an extreme degree of anæmia, or by evidences of the hemorrhagic diathesis. 2. Before the injections a prolonged use of drugs is necessary (these drugs are not mentioned by name), in order to act upon the contractile elements of the spleen, and so diminish the amount of blood in the organ, and, as far as possible, to render narrower the lumen of the vessels; the application of an ice-bag over the spleen is especially useful a few hours after and before the injection. 3. Fowler's solution is the most satisfactory drug to inject. Mosler states that he has recently had very good results following on the injections in enlarged leucæmic spleens. In one or two cases in which the disease proved fatal there was shown to be considerable thickening and constriction of the capsule, and Mosler is of opinion that this contraction has a favorable result not only by producing a general lessening in size of the spleen, but also by checking the leucæmic process, thus considerably improving the prognosis.

The Surgery of the Liver.—Professor Tansini, of Modena, recently performed total extirpation of a hydatid cyst of the liver, at the same time excising a portion of that organ. The hemorrhage was controlled with some difficulty, and the patient, a woman, was up and about in less than a fortnight.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, February 7, 1891.

SHOULD A POOR MAN STUDY MEDICINE?

A GENERATION ago a question such as the above would have laid the propounder open to the imputation of mental deficiency. As well might one have asked whether a poor man should work for his living. But to-day things have changed, and we venture to affirm that many, if not most, of our readers have already answered this question in the negative. Formerly an honest, hard-working, educated physician, with good health and the necessary perseverance, was certain of success in his calling. His knowledge was his capital, and he was always able within a short time to turn this to his own advantage as well as to that of his patients. But what is the case now? A man may be a veritable encyclopedia of medical knowledge, his acumen may equal that of any of the masters of the therapeutic art, and his industry may send a blush to the cheek of the proverbial ant, yet if he lack the one essential his other talents will avail him nought. A young man who is to succeed in the practice of medicine to-day must not only be industrious, talented, and well educated, but he must also possess the qualities that make the successful man of affairs, he must be alert to see and profit by anything that can be turned to his own advantage and not be too tender of the sensibilities or the interests of his competitors; in other words, in the expressive language of the time, he must be a "hustler."

The cause of this change in the conditions of successful medical practice is not hard to find, indeed it is so evident to the most superficial student of the economic side of our profession that we feel almost as though we were insulting the intelligence of our readers by even alluding to it. It is, of course, the dispensary evil. The profession is not overcrowded, that is to say, it is not overcrowded with good men, but the competition with the dispensaries is too great for most men to struggle against with any hope of success. We have no fresh arguments to introduce in support of this assertion, it is too self-evident to require any. But familiarity with wrong-doing sometimes blunts the sense of justice, and so the following picture of one of the pauperizing institutions in our city may seem at first glance overdrawn, but a little reflection will convince almost anyone of its faithfulness to the facts.

During the past summer the editor of an esteemed contemporary in the West paid a visit to New York, and while here went the round of the most important dispensaries. How these institutions impressed him the following will show. We give his exact words, suppressing only the names of the clinics, for his remarks apply to all, and would that they might be heeded by all!

"We had an opportunity recently," he says, "of visiting some of the hospitals and clinics of the great metropolis. It was while the International Congress was in session, so that very few of the most prominent operators were to be seen. But this did not prevent our getting an insight into the workings of the institutions, clinics, etc. The latter presented many features of especial interest. The buildings of the two largest, being comparatively new, the appointments and facilities for clinical teaching and for handling the large number of patients in attendance daily are of course of the latest and most approved order. But what was most striking, outrageous as it is, was the great number of well and fashionably dressed, evidently well-to-do people, both male and female, who applied for free treatment. It appears that the anxiety for abundance of material is so pressing that there is hardly any discrimination in this respect. At the —— on Tuesday, August 12, there were five hundred and sixty-eight patients, and, judging from their appearance, we venture to say that three-fourths, at least, of them were abundantly able to pay for private medical service. We have, of course, heard the numerous complaints that have been awakened among the New York physicians on this account, but we were not prepared to witness the spectacle presented there, of gayly-attired, semi-aristocratic humanity going in droves, petitioning for free prescriptions, free medicines. A notice of the presentation of a beautiful prize-etching to the patient who had made the most visits in a month would have surprised us none at all."

Is it any wonder that young men whose means are small often lose heart after struggling for a time against so powerful and so unscrupulous a rival as every dispensary is? If he has wealth he can wait and patients will come to him slowly, or if he is possessed of the gift of "push" he can perhaps work into a dispensary himself and thereby convert it into an ally instead of a rival. The esteemed contemporary from whom we have just quoted, after telling of the large and lucrative practice enjoyed by the dispensary visited, wishes to know what we are coming to. "The profession of New York," he says, "would be justified in arising in emphatic and effectual protest against such wholesale diversion of their revenues. Physicians are swindled and beaten out of an undue proportion of the fruits of their labor already by the public in general, so that it would appear but seemly for the profession to avoid and suppress, as far as possible, this rapidly increasing source of pecuniary loss through a channel of its own making."

Very true. But how is it to be done? And until it is done should a poor man study medicine?

REMINISCENCES OF ARMY MEDICAL LIFE.

IT is a well-understood fact in historical literature that no writer can faithfully chronicle the events of his own time. He may, indeed, give an accurate narrative of what happens, but he is too near the scenes of action, and

too much a part of the actions themselves and of his own times, to fully understand the relation of one event to another. Hence some of our most valuable historical pages are penned long after the heroes and heroines of them have turned to dust. The history of our own Civil War is a notable illustration. The works of Greely, Abbot, and Pollard have nobly fulfilled their purpose, but the true history of the war is yet to be written. The historian of the future must consult the *Century* War Papers, the numerous pamphlets and newspaper articles which are cropping out from time to time, and must wait at least another quarter of a century before he can properly attempt his task.

One side of army life has not been greatly written about. We refer to the services rendered by the volunteer medical force, by men who have since settled down to private practice, and who have a perfect mine of valuable information at their disposal. Much of it, indeed, may be of interest primarily only to the survivors of their own companies and regiments, but it is from just such detailed sources as these that authentic history is compiled.

Dr. W. W. Potter, of Buffalo, has published in the *Buffalo Medical and Surgical Journal* some very interesting reminiscences of this nature. A reprint lies before us, and we have found its perusal very interesting. "It is an undeniable fact," he says, "that the Medical Department was very near to the hearts of the millions of patriotic people who, while compelled to remain at home, contributed with lavish hands their means and substance for the successful prosecution of the war." This is indeed true, and the public is still glad to read such matter as Dr. Potter has written, giving the experience of daily life in army field hospitals. Many emergencies arose for which no possible provision could have been made, and native ingenuity had to supply the deficiency. On one occasion the doctor performed a consecutive amputation of thigh and arm, out in an open field, during a rain-storm, with no other protection than a rubber blanket held by four men over him and his assistants, and the patient recovered. "It was, moreover, a matter of experience that recoveries were more prompt, not to say more certain, when the soldiers who were disabled by curable diseases were treated in field hospitals. . . . The hygienic surroundings, too, were usually superior to those of large general hospitals, and besides, the sick treated in tents have an incomparable advantage in being able to obtain plenty of fresh air without the dangers of a draught."

We learn that during the war thirty-two medical officers were killed in battle or by guerillas or partisans, nine were killed by accident, and eighty-three wounded in action, of whom ten died. The total cost of the maintenance of the Medical Department of the Army, 1861–65, exclusive of salaries, was over forty-seven and one-third millions of dollars.

We trust that Dr. Potter's contribution to the history of the war will impel many others who served in the Medical Department to bring forward their store of information. All may not have kept such accurate records as the one from which we have quoted, but everyone can make a valuable contribution. We congratulate Dr. Potter that the story of his life in the field with the Army of the Potomac has been so entertainingly told.

CALIFORNIA AND OLD AGE.

Dr. P. C. Remondino, of San Diego, Cal., has written an interesting book upon climate and longevity, which has some practical interest, particularly for the Pacific coast. Dr. Remondino's gospel, as promulgated in his book, is that the art of prolonging life has made but little progress in the past hundred years, that the most important single factor in securing longevity is climate, and that the most favorable climate for longevity is Southern California. There is a smacking of business in this climax which makes one a little suspicious of the doctor's judgment, although we have no positive facts for denying that a residence in California promotes immortality.

Dr. Remondino, however, makes some specific statements which will hardly go unchallenged. He informs us that "a climate like that of California must, from the free access of sea air, possess an immunity from heart and kindred diseases, and the character of its soil must give to its inhabitants a like immunity from cancer!" As a matter of fact, in the twenty southern counties of California there were, during the year 1879–80, 91 deaths from cancer and 124 deaths from diseases of the heart and circulatory system. These occurred in a total of 2,621 deaths. In an Eastern State—Vermont—there were 183 deaths from cancer, and 320 deaths from heart and circulatory diseases in a total mortality of 5,024; so that the ratio, though slightly favorable to California, is not much below in average.

Our author adds that "California has, without exception, considering the extent of its coast, the driest and warmest soil that is to be found in any practically habitable portion of the globe. It has the hardiest, longest-living, and healthiest population imaginable."

If we remember correctly, the Tenth Census gives California, outside of San Francisco, a death rate of over 12 per 1,000, and this is admitted to be a very imperfect census of deaths. Other localities in this country have proclaimed a much lower death-rate than this.

Dr. Remondino's additional assertions that in California arterial changes are rare in the aged, and that atheroma of vessels, calcareous changes, apoplexy, aneurisms, gangrene, etc., are rarely found, must be received with much scepticism in view of the facts above given.

MEDICAL CANNIBALISM.

The New York daily papers of January 27th contain an announcement to the effect that "a dispensary has been organized on the West Side by young graduates of Bellevue and the Columbia Medical Schools. It is to be known as the 'Bloomingdale Clinic,' and will be located for the present at Ninety-eighth Street and Amsterdam Avenue."

Our views on the subject of these new dispensaries are well known. We claim and contend that they are not needed by the poor people of this city, that they tend to pauperize the people, and defraud the doctors of their rightful fees.

There are already far too many such so-called charitable institutions, and the present case seems a particularly aggravated one; for the doctors are themselves setting up the dispensary and warring upon the livelihood of their professional brethren. It is claimed that there is

no dispensary on the West Side between Sixtieth and 130th Streets. Is there need of one? Are the Roosevelt and Vanderbilt clinics too small to care for the poor (and well-to-do) within a radius of thirty or forty blocks? Does the Manhattan Dispensary complain of over-crowding?

Some excuse may be made for the medical men who do public work in the existing institutions which are under the care of trustees. They very regretfully say, "If we did not do this the directors would speedily find physicians who would gladly fill our places. We will refrain from indiscriminate public service if all other physicians will do likewise."

Are the young physicians who are about to organize the Bloomingdale Clinic actuated solely by a desire to do good to the very poor of the neighborhood? If so, let them seek these people in their homes, or treat them without fee at their offices. Let them do this charitable service unostentatiously, and all honor to them for it. We may have been misinformed in this matter. We hope that we have.

And while we are on this not altogether pleasant subject of hospital and dispensary abuse, let us give a thought to those patients who are under treatment by their family physician, but who, attracted by the name and fame of the *institution*, go to it in order to ascertain "whether their physician is giving them the right treatment." There are many such who apply at every dispensary. Possibly the medical attendant has advised operative procedure, and they go to the hospital to ascertain whether it is, or is not, justifiable. Does the dispensary physician do his whole duty by the family physician in every such case? We hope that he does. Does he ever, by "damning with faint praise," direct the patient, whose case is possibly an "interesting" one, to his own hospital service? We hope that he does not. The ground of vantage is all on the side of the consultant. If he fails to be straightforward and honest in his dealing with his absent medical brother, he deserves all the exposure and public reproach which can be brought upon him.

VITAL STATISTICS OF THE HEBREWS IN THE UNITED STATES.

The Census Office has recently published a bulletin containing a number of statistics concerning the Jews in this country. The statistics were obtained by means of a special inquiry addressed to about 15,000 Jewish families throughout the country, who had been in America at least five years, and answers of a satisfactory nature were obtained from over 10,000 families, including nearly 70,000 individuals. In many respects the figures obtained corresponded closely with the result of a large number of investigations into the vital statistics of Jews in Europe, yet there were some important, though as yet slight, modifications caused by the changed conditions obtaining in this country.

The number of males among the Hebrews was found to be considerably larger than that of females, the proportion being as 109.53 to 100, the figures for the general population being 103.57 males to 100 females. There are two points brought out by these tables which are opposed to the popular impression as to the members of this race; these are that there is a comparatively low marriage rate and a low birth-rate among the Hebrews in this country. The marriage-rate was only 7.4 per 1,000 annually, as compared with 18 to 22 per 1,000, which is the average rate among the general population in the Northeastern States. In New York City and vicinity it was above the average for that section, being 8.94, but was below the average in the Western and Southern States. The average age at marriage is greater among the Jews than among the general population, and these two facts will serve to explain for the most part the second point to which we just referred, namely, the low birth-rate. The average number of children was 4.66 for each mother. Those mothers who were born in the United States average only 3.56 children each, those born in Germany 5.24, those born in Russia and Poland 5.63, those born in Hungary 5.27, and those born in Bohemia 5.44, figures which show a diminished fertility in the women born in this country. Even this comparatively low birth-rate seems to be diminishing, since there is a falling off in the figures for each of the five years embraced in the investigation, except the last. The number of Jewish children under five years of age is less than it is in the average population of the country, excluding the negro population, in the proportion of 9 to 13, while from five to fifteen years it is greater in the proportion of 29 to 23.

The death-rate among the Jews is very low, being only 7.11 per 1,000, a little more than one-half the annual death-rate among other persons of the same social class and conditions of life in this country, yet this rate is progressively and rapidly increasing. For example, in 1885, the number of deaths reported among the 10,618 families was 332; for 1886, 359; for 1887, 387; for 1888, 442; and for 1889, 542. Among the most active of the causes of death were diphtheria, diarrhœal diseases, diseases of the nervous system (and especially diseases of the spinal cord), diseases of the circulatory system, urinary system, bones and joints, and of the skin, while the mortality of Jews was relatively less from the tubercular diseases, including consumption, scrofula, tabes, and hydrocephalus, than the other peoples with whom they are compared.

The average death-rate is greater among females (7.16) than among males (6.47); but this excess of deaths among females occurs after fifteen years of age, the rates under fifteen being for males 10.64, and for females 9.15. Among males the general death-rate is greater among those whose mothers were born in the United States, and least among those whose mothers were natives of Russia or Poland. When, however, the death-rates of the living male population between fifteen and forty-five years of age are compared, it is found that the average death rate was 3.10, while for those whose mothers were born in the United States it was 1.98, for those whose mothers were born in Germany 2.86, for those whose mothers were born in Russia and Poland 1.59, and for those whose mothers were born in England and Wales 6.32.

The death-rate among the native born of native-born parents was 9.15, and among the foreign born, 7.61. Between the ages of twenty-five and forty-five the death-rate among single males is decidedly greater than among married males. For females between the ages of twenty-five and thirty-five the death-rates are for the single 2.48, and

married 4.55, indicating the increased dangers due to conception and parturition; but among females over thirty-five years of age the death-rate is greater among the single than it is among the married.

The facts of most interest and of greatest importance brought out by the statistics are the progressively diminishing birth-rate and the progressively increasing death-rate. If these continue to decrease and increase respectively the time must come when immigration will fail to supply the deficiency, and the race will then be actually threatened with extinction.

THE LYMPH AND THE CORONER.

The recent notification, by one of the coroners of this city, that all cases of death from the use of Koch's lymph shall be duly investigated by him, has rightly occasioned much comment in medical circles. The grounds for such an action are by no means clear, nor is any possible good which can come of it made manifest. The opinion of the Corporation Counsel, upholding the right of the coroner to institute such proceedings, is open to serious question. The statute defining the functions of the coroner has no possible bearing upon the point at issue. The law provides that the duties of this official pertain only to such cases of death in which there is reason to suspect criminal intention or criminal incapacity as the cause of said death. There is no other interpretation to be made of the following clause: "Whenever a coroner is informed that a person has been killed or dangerously wounded by another, or has suddenly died under such circumstances as to afford a reasonable ground to suspect that his death has been occasioned by the act of another by criminal means, or has committed suicide," it is the duty of the coroner to issue a warrant and take testimony. It can hardly be claimed that there is any foundation for suspicion of criminal motive, culpable ignorance, professional incapacity, or unlawful assumption of responsibility on the part of those gentlemen whose patients have died while under treatment by the lymph. Even if it were scientifically proven that the use of the lymph had been in any way responsible for the death of the patient, the case would no more be one for a coroner than would any other in which a fatal result occurred, consequent upon the use of any medicine or remedy considerately prescribed with the view of ameliorating or curing disease. The law recognizes the right of the licensed and educated physician to use his own judgment in prescribing for his patients, and does not hold him accountable for results unless criminal motives, unlawful intention, or culpable ignorance are charged. In cases of doubt the Health Board is the only proper authority to take the matter in hand and, if necessary, to turn it over to the coroner. The public has heretofore been so amply protected by the watchful eye of the Registrar of Vital Statistics as to make it entirely unnecessary for any coroner to magnify his office by acting as a self-appointed censor of strictly professional work.

Allowing the right for the coroner to assume such new functions, what good can come of his investigations?

Can it be possible that he shall attempt to decide upon the merit or demerit of a method of treatment of which necessarily he knows nothing, and concerning which the leading pathologists here and abroad have as yet been unable to form a positive opinion? Especially absurd would be such an attitude in view of the fact that no case of death, in this country at least, has been directly chargeable to the lymph. Even in those reported from Berlin, it has been by no means absolutely proven that the same unfortunate results might not have occurred independently of the use of the new fluid, and in the natural course of a disease with well-known fatal tendencies. There are many points connected with the lymph which are yet unsettled; they are still on trial, but not before a coroner's jury.

PREACHING AND PRACTICE.

The *Journal of Inebrity* has demonstrated, to its satisfaction, that alcohol is always a poison, and never a food, that it causes neuroses in the young, angiopathies in the old, and psychoses at all ages; that inebriety is always a disease, and generally curable at the establishments of the inebriate specialists. With the accomplishment of the above modest tasks, the *Journal* now proceeds to convert the general profession to habits of total abstinence. "The physician," it says, "of all others should be the last one to use spirits in moderation or excess. The use of alcohol as a beverage is direct evidence of ignorance of the teachings of modern science, and failure to keep up with the growth of medical advance."

The *Journal* is right. Indulgence in alcohol in any form is antagonistic to the ideal and perfect life as led by the inebriatorists and other world-betterers. So is eating pie and sitting up late nights and writing too many medical articles. It is hard to be perfect, but every one can attain an ideal in some direction. We advise every one of our readers to be a total abstainer.

But we do this on physiological grounds and not because the physician must necessarily practice all that he preaches. We cannot admit that this moral principle applies to the medical profession. The physician must direct his patient to do the very best thing possible for the said patient's health, but he need not take a dose of calomel every ten days because he had advised this, nor need he deny himself the rare and temperate consolation of tobacco because his patient is forbidden its use.

But alcohol is all wrong, and we hope the *Journal* will continue its propaganda against it.

THE PRIVATE HOSPITAL SYSTEM.

One of the outgrowths of modern medicine is the private hospital system. While these establishments have been common enough in Europe for some time, they are a comparatively new feature in this country. The last ten years have witnessed the equipment of more private hospitals than did the whole previous half-century. In this city there are certainly more than a dozen such institutions, not including the private "retreats" for the insane.

Naturally, it is the general surgeon and the gynecologist who have the most of these, but there are ophthalmologists, dermatologists, neurologists, and others, who have their own quarters for their private patients.

The private hospital system is a natural development from the necessities of practice and the limitations of

public hospitals. Some patients dislike the idea of going to a general hospital under any conditions. Besides, these institutions are owned and conducted by boards of laymen who put such restrictions upon the attending medical men, that often their best services must be rendered gratuitously to patients who could readily pay a proper fee. But, furthermore, the number of competent men with wide reputation is relatively large, and the number of appointments to hospitals is small. These appointments are made, to a considerable extent, by favor rather than by merit. Hence the private hospital becomes a necessity; or, otherwise, competent surgeons must turn severe cases over to colleagues who are no more competent.

It has been found that when the private hospital is a success, it is a very great success from a pecuniary point of view. As long as justice is done to patients this is a commendable fact, for it adds to the pecuniary resources of the profession. And, however painful it may seem, it is true that those pursuits which furnish the greatest pecuniary rewards attract the best talent, and the highest class of intellect. If the organization and work of the medical profession become so adjusted that it can secure better practical results to the patient and better material reward to the physician, the profession will reach a higher plane. The private hospital system, when properly used, seems to be a help in this direction. It has its abuses, but then we must trust to an enlightened professional opinion to guard against these.

News of the Week.

Metropolitan Medical Society.—The following officers have been elected for the ensuing year: *President*—I. P. Oberndorfer, M.D.; *Vice-President*—I. Oppenheimer, M.D.; *Corresponding Secretary*—Henry S. Stark, M.D.; *Recording Secretary*—A. N. Strouse, M.D.; *Treasurer*—T. J. McGillicuddy, M.D. Meetings are held bimonthly at members' residence. Membership limited to seventy-five.

Special Lectures by Professor T. Gaillard Thomas.—Professor T. G. Thomas will deliver four lectures on "The Pathology of Uterine and Ovarian Diseases," at eleven o'clock on the mornings of February 27th, March 2d, 6th, and 7th, at the College of Physicians and Surgeons. They will be well worth hearing.

A State Institution for Drunkards.—The Massachusetts Legislature enacted a law two years ago for the establishment of a State institution for drunkards, or to use the scientific euphemism, inebriates. The statute incorporates this institution, giving $150.000 for 200 beds, and provides that certain habitual drunkards, or, in the words of the law, dipsomaniacs and inebriates, may be committed to it in a manner similar to the present commitment of the insane to insane asylums. It may be considered as between a prison and an asylum. Although legally an asylum, or rather, in the words of the statute, a hospital, it is regarded by the trustees as medically a prison. Any person there confined, except voluntary patients, may be held as long as the trustees think best, within limitations similar to those in force in regard to inebriates in insane asylums. The trustees have bought a farm near Foxborough, with about thirty acres of good farming land, and have made contracts for the erection of buildings on the cottage plan. The Superintendent is Dr. Marcello Hutchinson. Such an institution was started in this State some years ago at Binghamton, but it utterly failed to accomplish its purpose.

Lunacy is not Increasing in the State of New York in proportion to the increase in population. Such is the happy news furnished us by the State Commission in Lunacy. In New York City and Brooklyn the relative increase is particularly small. A study of the commissioners' statistics upon which their conclusions are based shows that the facts are as yet a little inadequate for positive conclusions.

The New Era in Medical Teaching.—The Ohio Medical University is a new institution recently incorporated in Ohio, to be located at Columbus. The new university will consist in a department of medicine and surgery, a department each of dentistry, pharmacy, midwifery, and a training-school for nurses; and will be supplemented by a large new hospital, the gift of a number of the wealthy philanthropic Protestants of that city, and which, it is said, will cost about two hundred thousand dollars when completed. One of the prominent features of the new university will be the abandoning of the system of instruction by lectures, and adopting, instead, the plan of class teaching, similar to the methods now employed in the literary colleges. A graded course of three years of nine months each is to be adopted, which will include daily examinations and grading of the students, thus doing away with the necessity of a final examination.

The Misfortunes of a Quack.—The Paris correspondent of *The Lancet* writes that a quack was convicted and heavily fined for illegally practising medicine at Albertville. No sooner did this happen than several of his numerous friends and patients opened a subscription list in a local café, with the view of meeting the fine and legal expenses. The subscription list was, however, seized by the police, and those who had so far subscribed were prosecuted by the State and fined. But the staunch defenders of the quack determined not to let the matter rest here. They appealed to the higher tribunal in Chambéry, where, however, the decision of the lower court was confirmed. This tribunal, in giving judgment, laid it down that the prohibition enjoined by the law against opening a public subscription for the purpose of covering the expenses and fines inflicted by judicial authority and judgment in matters criminal and *correctionnelle* applies to the illegal practice of medicine. The defendants were now further mulcted in the expenses of appeal thus dismissed. Our quack will hardly retire from practice after this manifestation. The proverbial coach and four of O'Connell will carry him through yet.

Liability of Members of Societies for Subscriptions.—The British Gynecological Society is said to be in a prosperous condition, but it has had to have recourse to rather extraordinary measures in order to be so. It has instituted legal proceedings to compel recalcitrant members to pay up. It has the satisfaction of having obtained a judicial decision validating the liability of Fellows in this respect.

The Dangers of Liqueurs.—At the Académie de Médecine, M. Lancereaux has made a report on the dangers of certain alcoholic drinks made from essences, which were being very freely used in France to-day. Those who suffer from absorption of essences present different symptoms to those usually met with in ordinary alcoholic poisoning. The individual experiences at the hour of sleep painful sensations of the limbs like pins and needles, which prevent all repose, anæsthesia of these parts follow, and the reflex of the patellæ is notably diminished. The principal character of these symptoms is that of being always symmetrical. Mental troubles supervene very rapidly, and paralysis is more frequent from essence drinking than from alcohol. What is rather remarkable is the fact that about eighty per cent. of the patients M. Lancereaux examined were women. The essence known as créme de menthe is very popular with both sexes in the country.

A Suit for a Ruptured Perineum.—The money value of the perineum came very near being judicially determined by a Kansas City court. A physician of that town was sued for $11,000 damages because he allowed the perineum of the plaintiff to be ruptured and did not subsequently sew it up. The plaintiff withdrew the case.

Shall Pupil Nurses be Paid?—This question has been repeatedly discussed of late, but has been generally answered in the affirmative. The Training School for Nurses of Harper Hospital proposes to abolish the practice, to give the pupils only eight hours' work, and to let them have one-fourth of what they earn in private nursing.

Novel Surgical Treatment of Exophthalmic Goitre.—Dr. Lencke, of Hamburg, reports two cases of exophthalmic goitre in which surgical treatment of goitre produced "great relief" of symptoms. The first patient was a lad of seventeen, who had the classical symptoms of the disease—rapid heart, palpitation, prominence of the eyes, and goitre. He came under treatment on account of a sudden access of the swelling, which by the pressure it exerted produced great distress with extreme cyanosis. The heart was rapid and irregular, no rest or sleep could be obtained, and the patient was in imminent danger of asphyxia. Tracheotomy was performed, and a week later one-half of the tumor was extirpated. The operation was accompanied by much hemorrhage, which, however, stopped spontaneously, and recovery was uninterrupted. The symptoms rapidly vanished, the exophthalmos disappearing, and the heart becoming quiet and regular in action. The improvement was maintained until the time at which the paper was written.

The second case was that of an older patient, and was attended with similar results.

A Big Medicine Man.—A full-blooded Sioux Indian has just graduated in medicine at the Boston University.

Typhoid Fever in Albany.—The daily papers have recently contained sensational reports of the prevalence of typhoid fever of malignant type in Albany. It is true that more cases are reported as typhoid fever this year than usual, yet it is a question whether the disease is true typhoid, as many of the cases are extremely atypical in their symptoms and course. The cases are not of a virulent nature but are in the majority of instances mild, and the death rate in this city is no greater than usual. Gastric disorders and diarrhœas are rather extensively prevalent, though the course of them is not definitely known. It is very probable that some of these are reported as typhoid fever. It is said that the river water is impure, and much of the sickness is attributed to this cause, yet it is doubtful whether this is the case, for the water-supply is the same as it has been for several years, yet no unusual amount of typhoid fever has been reported until this year. Two years ago, this coming spring, a somewhat similar outbreak occurred in the shops of the New York Central Railroad at West Albany. Most of the cases here were not really typhoid fever, yet a few were typical instances of the disease. The water supply at this time was from other sources than the river. Since then, however, river water has been brought in and the drainage has been improved, and this winter that part of the city is free from the fever reported elsewhere.

The American Electro-Therapeutic Association was organized on January 22, 1891, at the Academy of Medicine, No. 17 West Forty-third Street, New York, by the adoption of a constitution and by-laws, and the election of the following officers: *President*, G. Betton Massey, M.D., Philadelphia, Pa.; *Vice-Presidents*, William James Morton, M.D., and Augustin H. Goelet, M.D., New York; *Secretary*, William H. Walling, M.D., Philadelphia, Pa.; *Treasurer*, George H. Rohe, M.D., Baltimore, Md.; *Executive Council*, Horatio R. Bigelow, M.D., Philadelphia, Pa.; Franklin H. Martin, M.D., Chicago, Ill.; William F. Hutchinson, M.D., Providence, R. I.; Frederic Peterson, M.D., New York, and Channcey D. Palmer, M.D., Cincinnati, O. The object of the association, as stated in Article Second of the Constitution, is, "The cultivation and promotion of knowledge in whatever relates to the application of electricity in medicine and surgery." The association starts with a strong and vigorous membership, and has every prospect of a most useful and successful career. The next meeting will be held in Philadelphia, in September of this year. William H. Walling, M.D., *Secretary*, 2005 Arch Street, Philadelphia, P.

The President of the United States has Received Some Medicine and placed it where it will presumably do the most good. The medicine consisted of five vials of Koch's lymph sent him by Minister Phelps. Two vials were sent to Surgeon-General Hamilton, of the Marine Hospital Service, Washington, and one vial each to the Polyclinic Hospital, of Chicago, the Charity Hospital, of New Orleans, and the City Hospital, of Indianapolis.

Suit by a Hospital.—Roosevelt Hospital has brought suit against the elevated railroad for $100,000, on account of damage to the institution done by the noise of the trains.

Medical Legislation for Texas.—The Committee on Medical Legislation of the Texas State Medical Association have drafted suitable bills, one to regulate the practice of medicine, and one creating a State Board of Health; and will present them to the Legislature early in the present session.

Medical Examiners for the State of Wisconsin.—The Wisconsin Legislature has recently passed an act creating three Boards of Medical Examiners, representing the Wisconsin State Medical Society, the Homœopathic Medical Society, and the Eclectic Medical Society of the State respectively. Each board is to consist of three members, who shall serve for three years, their terms being so arranged that one shall be retired each year, his place being filled by the appointment by the governor of a new member from a list of candidates submitted by the respective societies. These boards shall hold meetings for the examination of candidates on the second Tuesday of July, October, January, and April. The several boards must submit to the supervisor of medical examinations, who cannot be a practising physician, lists of questions for examination in the usual branches, and from these lists the supervisor will select at random the questions for each examination and present the same to the candidates. Each candidate must present to all three of the boards satisfactory evidence of good moral character, that he is more than twenty-one years of age, that he has obtained a competent common-school education, that he has studied medicine three years, including two years in some legally incorporated medical school, and that he holds a legitimate diploma conferring the degree of Doctor of Medicine, or a diploma or license conferring the full right to practise all branches of medicine and surgery in some foreign country. Each member of these several boards shall receive a compensation of ten dollars a day for each day actually spent in the performance of his duties as examiner, and in addition shall be paid for legitimate expenses. The secretary of each board shall receive the additional sum of three dollars for each and every candidate examined. The supervisor of medical examinations, who shall not be a practising physician, is to be appointed by the governor and will hold office until his successor shall be appointed. He is to receive one dollar for each license to practise medicine granted by the boards. No one, not previously entitled to practise medicine under the existing laws of the State, will be permitted to practise after the first day of July, 1891, unless he has received a license from one of the legally constituted boards of medical examiners. Any candidate who fails at one examination will be allowed to appear before the board again after an interval of six months.

The New York Academy of Medicine.—At a recent meeting of the Pediatric Section of the New York Academy of Medicine, Dr. A. Caillé was elected Chairman, and Dr. W. L. Carr was re-elected Secretary. At the annual election of officers of the Orthopedic Section of the Academy of Medicine, Dr. Samuel Ketch was elected Chairman, and Dr. T. Halsted Myers, Secretary, for the ensuing year.

The Centennial of the Connecticut State Medical Society.—This society will be a hundred years old in October, 1892. Arrangements are now being made to observe the occasion by means of a grand reunion of the profession of the State. Dr. Gurdon W. Russell, of Hartford, has been appointed to prepare a medico-historical sketch of the colonial period and subsequent years up to 1792, and Dr. Francis Bacon, of New Haven, has been invited to write the subsequent history.

Professor Rudolf Virchow's seventieth birthday will be celebrated with due honors on October 13th of this year. Professor Waldeyer, Drs. W. Reiss, Bartels, Langerhaus, Ad. Meyer, and Professor B. Fraenkel have issued a circular inviting friends and admirers of the great pathological anatomist to subscribe to a gift of honor, which is to take the shape of a golden portrait medal (about 19 centimetres in diameter).

The American Nurses' Association.—The object of this organization, having its headquarters in New York, is a union for protection, provision in sickness, an annuity fund, burial insurance, and friendly promotion of the professional interests of nurses; also it is proposed to have a loaning fund which may be drawn upon by members when disabled in the pursuit of their regular occupation.

Regulating Dental Practice in Connecticut.—The action of the several medical societies in this State which have taken steps to have a bill presented to the General Assembly to prevent the practice of medicine by quacks, has aroused the dentists, and this year an effort will be made to secure the passage of a bill to regulate the practice of dentistry.

The Canadian Samson.—Canada has a man who is credited with lifting 3,993 pounds, almost two tons, without any harness. He is 5 feet 9½ inches tall, and weighs about 240 pounds. With regard to his habits, he says: "I abstained two years ago from liquor and tobacco; before that, used to take them regularly. I am three times better off since then. I gained in strength enough to lift 700 pounds more in these two years. Liquor is a bad habit, anyway. Tobacco, too much of it, is bad. I am three times better off since I gave them both up." He eats five or six pounds of meat daily.

Bequest to a Hospital.—The Springfield (Mass.) Hospital, by the will of the late Mrs. Catherine H. Lombard, receives a bequest of $20,000.

The Dietetic Gazette is now edited by Dr. Simon Baruch, of this city, and is published monthly. Its pages contain much that is interesting and practical.

Dr. S. S. Strong, of Saratoga, proprietor of Strong's Sanatarium, died on February 1st, aged seventy-eight years.

The Actual Dose of Parataloid must be somewhat less than one six-hundredth of a grain.

Quaker City Journalism.—Our esteemed contemporaries of Philadelphia are getting somewhat noted for their eccentricities in journalism. Some time ago one excellent journal started out with the announcement that it would hereafter publish no "Reports of Societies," on the ground that such reports were not interesting or useful matter. Another contemporary has recently announced that hereafter it will not publish regularly any editorials. We are told that the editorial space "is often an excuse for foisting upon a subscriber much useless material, and for this reason the pages usually so employed in the past in the *News* will be taken up with notes on current literature." It only remains now for some enterprising Philadelphia medical journal to abolish its original department, and shut down upon its correspondence; we shall then see what constitutes an interesting medical journal from the Quaker City stand-point.

The Chemistry of the Tubercle Bacillus.—At the clinic of Professor Nothnagel a very interesting investigation on the chemical composition of the tubercle bacillus has been carried out by Dr. Hammerschlag, who had commenced his studies on the bacillus at Professor Nencki's chemical laboratory at Berne. Two analyses of two different culture series were made. The cultures were 0.2–3 months old, and 7.5 and 2.2 grammes moist bacteria were obtained for the analyses. They contained between 88.7 and 83.1 per cent. water, between 28.2 and 26.2 per cent. substances soluble in alcohol and ether, *i.e.*, lecithin, fats, and a poisonous substance which, injected subcutaneously into guinea-pigs, produced clonic spasms of the muscles, acceleration of pulse and respiration, and finally general convulsions and the death of the animal, from twelve to fifty-one hours after the injection. The residue which remained after the extraction with ether and alcohol, contained an albuminoid body and cellulose. Therefore the tubercle bacilli seem to differ from other bacteria by the high percentage of substances soluble in alcohol and ether, as they contain between twenty-six and twenty-eight per cent., while bacterium termo contains only 7.3, Friedländer's diplococcus only 1.7, the bacillus anthracis only 7.8 per cent. It has been found that the presence of carbohydrates and glycerine is necessary for the growth of the bacilli, and that albumins alone are not sufficient as nourishing media for the tubercle bacillus, which differs thereby from the other bacteria. By experiments on rabbits it was proved that a poisonous albuminoid body is formed in the cultures by the bacilli, which (the dose used varied between 0.2 and 0.4 gramme) produced, a few hours after the injection, a rise of temperature amounting to 1° or 2° C., lasting for one or two days, without any other effect, even after repeated injections. The glycerine bouillon cultures lost their virulence on being kept for eight months at a temperature of 39° C., but they retained their vital activity. In experiments made on animals with such cultures of eight months' standing, only negative results were observed with regard to the production of immunity in animals by such cultures, and Hammerschlag, Falk, and Charrin have failed to produce a protective inoculation.—*Lancet.*

Mr. Victor Horsley has resigned his position as professor-superintendent of the Brown Institution.

Lazaretto not to be Moved.—The movement for the removal of the quarantine station for Philadelphia and the entire State received the unqualified disapproval of the Board of Health at a special meeting of that body recently called for the consideration of the subject. Dr. Ford, former president of the board, as chairman of the Lazaretto and sanitary committee, submitted a report characterizing the proposed plan as a scheme for private interest involving an enormous outlay of public money, and calling upon both branches of the municipal legislature to use their influence for the defeat of the bill now pending in the State Legislature, which was adopted by the board. A memorial was also sent to the State Board of Health asking their co-operation with the local boards to secure the defeat of the measure, and setting forth reasons why the Lazaretto should continue to occupy its present site. Among the reasons were that no public necessity exists for its removal; that the present site is eminently suitable for a quarantine station and is better adapted to the requirements of the station than any other could possibly be; it has an unfailing supply of water from an artesian well, and has been supplied with every convenience at the expense of thousands of dollars, including a system of underground drainage. The friendly relations existing with the Breakwater station are also cited as a reason, together with the facts that no evil has resulted to surrounding districts, and that its removal would be an uncalled-for expense without a corresponding gain to tax-payers.

Pronounced a Leper in her Old Age.—A case of leprosy has been reported to the Wisconsin State Board of Health. The patient is a Norwegian woman who recently came from the old country. She is a resident of Buffalo County and has had leprosy for eighteen years. The woman has four adult children, but on none of them have symptoms of the disease appeared.

Against Refilling Prescriptions.—The Marion County, O., Medical Society recently decided to ask the Legislature to enact a law prohibiting druggists from refilling prescriptions unless ordered by the prescribing physician.

A New Theory of the Pathology of Chlorosis.—Dr. Scholz, of Bremen, advances a new theory and treatment for chlorosis. The deficiency of the blood in corpuscles and iron he regards as a secondary complication. The primary trouble consists in a contraction of the blood-vessels, which are, he says, too full, or in the condition termed by the older physicians "plethora ad vasa," the blood being—or becoming—abnormally serous. Long ago his attention was struck by the cold and livid condition of the skin in anæmic subjects, and he was led by this to employ hot baths, together with gentle friction, in the treatment, with the view of acting directly upon the skin, so as to improve the vitality and nutrition generally. The success of his first attempts was so marked that he was encouraged to persevere in this line of treatment, and he has since had many opportunities of extending his experience with it. Hot baths diminish the plethora by relaxing the tension of the vascular system, which is high, quickening the circulation, and thus relieving the palpitation, dyspnœa, and other symptoms. In thirty cases where the distress of the patient was very great Dr. Scholz has gone a step further and supplemented the hot bath by venesection.

Tapeworm as a Cause of Puerperal Fever.—Professor Paramuchi has reported a case of puerperal fever in which a very unexpected cause was brought to light—that is to say, the putrid remains of a tapeworm in the uterus. No untoward symptoms seem to have occurred until the tenth day after delivery, when the patient became feverish and prostrate and lost her appetite. Septic fever subsequently developed. Regarding the question of how the tapeworm came to be in the uterus, inquiries elicited the fact that a few days before her confinement the patient had been suffering from dysenteric symptoms, and, in view of her condition, had not taken any medicine. It is probable, says *The Lancet*, that the worm managed to migrate after delivery from the rectum to the vagina, and that there it died and became putrid.

Reviews and Notices of Books.

THE BIOGRAPHY OF EPHRAIM MCDOWELL, M.D., "THE FATHER OF OVARIOTOMY." By his Granddaughter, MARY YOUNG RIDENBAUGH. Pp. 558. New York: Charles L. Webster & Co. 1890.

THE appearance of this work has been awaited with no little interest by the profession, since the name of McDowell has long been a household word. Hitherto he has been to many a vague and unreal, though heroic character, but hereafter we shall feel as if we knew him intimately. The present biography is, on the whole, worthy of its subject. Although prolix and uneven, containing much that might be omitted as entirely irrelevant, the portion which is devoted to the life and deeds of McDowell himself (including Chapters III. to VII.), is of entrancing interest. Chapter V., containing the account of that memorable first ovariotomy, is tantalizing by reason of its brevity. But as we read that the operator himself left no written memoranda of his technique, we must accept the scanty record which is given. Only one-fifth of the work is devoted to the man himself, the remainder being largely a history (with a decided polemical tendency) of the development of ovariotomy, a subject which has already been discussed in monographs by different authors. The last hundred pages contain various eulogistic addresses, letters, etc. This work will meet with a warm reception from the American profession, since it sets forth the achievements of one whose fame is our common inheritance. Whatever literary defects the present memoir may possess, it serves worthily a noble purpose in perpetuating the grand character of one of the heroes of medicine. The type, binding, and, in fact, the *tout ensemble*, of the book are beyond reproach. An excellent portrait of McDowell and a picture of his memorable operation add to its value.

HYSTÉROPEXIE ABDOMINALE ANTÉRIEURE ET OPÉRATIONS SUR-PUBIENNES DANS LES RÉTRODÉVIATIONS DE L'UTÉRUS. Par MARCEL BAUDOUIN. Avec 22 Figures dans le Texte. Pp. x., 375. Paris: Lecrosnier et Babé. 1890. (Anterior Abdominal Hysteropexy and Supra pubic Operations in Retro-displacements of the Uterus. By Marcel Baudouin. With Twenty-two Illustrations.)

THIS volume is a model of French prolixity. No one but a Frenchman would think of writing a monograph on a subject which possesses interest only for a limited number of gynecologists. Not that it is without considerable interest as presenting an exhaustive study of the development of a single operation; we only protest against the excessive amount of details, by the omission of which the book might have been condensed at least two-thirds, with advantage to the reader.

The author's study of the literature of his subject has been most exhaustive, as will be seen in Chapter II., in which he reviews the history of hysteropexy (or, as we term it, "hysterorrhaphy") from 1859 to the present time. Ample justice is done to American operators, beginning with Sims. Some idea may be gained of the thorough manner in which the subject is treated if we state that sixteen different methods of intraperitoneal, and four of extraperitoneal fixation are described and their advantages discussed at length. Elaborate tables show that hardly a single case reported in any country has escaped the search of the diligent author. The illustrations are particularly clear and intelligible, and will constitute the most valuable feature of the book to the busy surgeon, who has not time to wade through the mass of description which accompanies them.

A Woman's Health Protective Society has been organized in Pittsburg, Pa. At present it is engaged in a crusade against tobacco-spitting in street-cars.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Eighty-fifth Annual Meeting, held at Albany, N. Y., February 3, 4, and 5, 1891.

W. W. POTTER, M.D., PRESIDENT, IN THE CHAIR.

FIRST DAY, TUESDAY, FEBRUARY 3D.

Inaugural Address.—The President, DR. W. W. POTTER, of Buffalo, expressed his appreciation of the high honor conferred upon him when he was elected President; referred to the Medical Examiners' Bill, which he said ominously signalled the last decade of the nineteenth century; expressed the opinion that it was an improvement on that originally proposed; that the Society should stand as a unit against any change in its provisions until it has been given a fair trial. In calling attention to suggested legislation regulating the practice of midwifery, he stated that in Erie County midwives were at present required to be examined by four or five physicians before being allowed to practise their art.

Appointment of State Medical Examiners.—DR. ROOSA moved that a special committee of five be appointed by the President to name fourteen physicians from among whom, according to the new law, the State Regents might select seven to act as State Medical Examiners. Carried unanimously. The President appointed later, Drs. Roosa, Sherman, Roe, Flood, and O'Leary.

Railroad Surgery.—DR. CLINTON B. HERRICK in this paper enjoined antiseptic surgery, divided railroad injuries, for convenience, into those of the head, of the hand and fingers, and those of the extremities. One should always save the thumb if possible. As bearing on the seat of amputation, he said great speed of the train might call for higher amputation.

A Stiff Finger Useless.—DR. C. T. POWERS strongly endorsed one point made in the paper, that it was useless to save a finger of a laboring man if it should afterward be stiff. The thumb, however, was very important, and should be saved if possible.

Objects to the Term "Railroad Surgery."—DR. MINTER thought railroad surgery did not differ from ordinary surgery, because railroad injuries did not differ from injuries produced by machinery, falls, etc. Injuries to the kidneys, however, were more likely to take place in railroad accidents, but there was no occasion for railroad surgeons organizing as a distinct body from civil surgeons.

A Report of Cases of Injury to the Knee-joint, with Remarks.—DR. HENRY FLOOD in this paper reported a case of injury to the patella, one of dislocation of the knee-joint, two of injury to the knee, one of fracture at the knee-joint; all of which illustrated the importance of two great principles in surgery, thorough drainage and absolute rest.

An Account of the Chronic Sequences of an Attack of Apoplexy.—DR. J. LEONARD CORNING read this paper. The paralysis was one-sided in the body, might be general, or localized in one limb or part of the limb; was usually on the opposite side from the cerebral hemorrhage; recovery of power might extend over weeks or months; might never be complete; the occurrence of contracture was an unfavorable symptom for complete recovery; we may assume that it is due to degenerative change in the pyramidal tract in the cord. Anæsthesia is much less persistent than motor derangement; it may give place to hyperæsthesia; temperature sense has in few cases been entirely lost; trophic disturbances and severe inflammation of joints sometimes take place; also associated movements, mental disturbances, usually in the form of dementia. Facial symptoms were also mentioned.

Committee on the President's Address.—THE PRESIDENT appointed on this committee Drs. Suiter, Daniel Lewis, and Minter.

Necrosis of the Ribs Complicating Pott's Disease.—Dr. Lewis A. Weigel reported a case of this somewhat rare complication of Pott's disease. The eighth, fifth, and sixth ribs were involved, the former perhaps by extension of the tubercular disease from the vertebræ in that immediate region, the fifth and sixth probably by burrowing of pus in this unusual direction. He exsected the necrosed bone.

Brief Notes on Gastrotomy, with Report of a Successful Case.—Dr. Charles T. Powers, of New York, read this paper. The case was one of cancer causing complete occlusion; the stomach was first fastened to the abdominal wound, and was opened on the fifth day; life was prolonged some months, when the patient died of the original disease. The indications for the operation in general were obstruction from various conditions, as tumors internal and external to the stomach, especially cancer; also obstructions in the pharynx and œsophagus. The operation was not a long one; he would use chloroform or ether, would operate early, increase alimentation very gradually; to prevent leakage was of greatest importance and seemed best accomplished by the double balloon cannula. The mortality in malignant cases had only slightly diminished since Dr. Gross had collected his statistics, in 1884, Dr. Gross giving twenty-nine per cent. of deaths, Dr. Powers twenty-seven per cent. in malignant cases, collected since 1884. In non-malignant cases, however, it had fallen to eighteen per cent. His statistics, which he did not claim to be complete, included ninety-nine cases.

Would Use Cocaine.—Dr. Minter, of Buffalo, said gastrotomy was considered an easy and simple operation in Germany, frequently enough performed, cocaine being for many reasons preferable to ether or chloroform.

The Electro-cautery in Surgery, with Special Reference to Its Use in the Nose, Mouth, and Throat.—Dr. David H. Goodwillie, of New York, presented a complete electro-cautery outfit for use in surgery, including saw, knife, wire loop, etc. No technical knowledge of electricity was longer necessary. Soon one would use in surgery electric power obtained only from storage cells or directly from the dynamo. The superiority of the electro-cautery wire, in the removal of naso-pharyngeal tumors, over the usual method by the knife was considered evident. He also used this instrument in removing the tonsils, tumors, etc.

Operative Procedures in Acute General Suppurative Peritonitis.—Dr. W. E. B. Davis, of Birmingham, Ala., selected this title for his paper, although it contained the statement that when general peritonitis had become suppurative it must prove fatal. Every case of septic peritonitis, he said, must become suppurative if time permitted. He had known cases of gunshot and other injuries of the abdomen result in suppurative peritonitis in twelve, twenty-four, forty-eight, and seventy-two hours. The necessity for an early operation was evident. The author referred to an operation which he had described in another paper, in cases of acute suppurative peritonitis where there was great intestinal distention with gases; paralysis was usually present, and could not be relieved by puncture with the needle. The viscera should not be taken out. He incised the intestine, let out the gas, and washed it thoroughly. The peritoneal adhesions were also broken up and the abdomen washed out.

The Progress of Cystoscopy in the Last Three Years.—Dr. Willy Meyer, of New York City, read an abstract of his paper. He confined his remarks to the progress which has been made in regard to the diagnosis and treatment of kidney diseases with the help of the cystoscope. The report of two cases of renal disease, which lately occurred in the speaker's practice, widely illustrated the advance in this line. In both Dr. Meyer had been enabled to make the diagnosis of suppurating kidney as well as establishing indication and prognosis of nephrectomy, by carefully observing the jets of urine which passed the urethral orifices. In one of the cases he had timed these jets on each side, and had thus made out that the work done by the diseased kidney was insignificant to that of its fellow. Nephrectomy was successfully performed by the speaker in both cases, and the specimen obtained proved the correctness of the points gained by cystoscopy, in every particular. The new French cystoscope, manufactured by Carrière, will further enable the cystoscopist to catheterize the ureters in an easy and simple way, and greatly help to increase the importance and value of this new field of surgical diagnostics.

A Plea for Rapid Dilatation, Holt's Operation, in the Treatment of Urethral Stricture.—Dr. F. R. Sturgis based his preference for rapid dilatation or divulsion in urethral stricture on three facts: 1. Avoidance of severe hemorrhage. 2. Avoidance of severe chill. 3. Less danger of septic poisoning.

Dr. S. D. Powell also expressed his preference for divulsion over internal urethrotomy, but with his own instrument devised nearly ten years ago.

Dr. Daniel Lewis preferred the bulbous bougie.

Dr. Minter preferred the urethrotome.

Dr. Cregor thought divulsion was liable to be followed by nervous symptoms.

A Case of Imperforate Anus of Eight Weeks' Standing.—Dr. William Hailes, Jr., treated this case by gradual dilatation, which was continued by the mother after the size had reached the point admitting her little finger.

A Contribution to the Surgical Treatment of Jacksonian Epilepsy.—Dr. Edward B. Angell related a case of Jacksonian epilepsy, affecting the arm centre mostly, which had progressed to an extreme degree, and led him to have an operation performed, removing, in the absence of definite lesions, a large part of the motor centres. The bone was replaced. Hernia cerebri developed, together with inflammatory changes, and the patient died in the third week.

Regarding Abolition of the Death Penalty.—A communication was read, received from Dr. N. M. Curtis, advocating abolition of capital punishment, and requesting the appointment of a committee to report to the Society on the subject.

The President appointed on this committee Drs. A. Jacobi, B. F. Sherman, and Wey.

Committee on Experimental Medicine.—Dr. J. G. Curtis, of New York, on behalf of the yet living members of this committee, read a report and asked that the committee's powers and duties be reaffirmed. The report was adopted.

The Prize Essay.—Dr. Eugene Beach read the report of the committee, signed by Drs. George F. Shrady, Daniel Lewis, and Beach. Four essays had been received in competition, all valuable, but the award was to that on "The Pathology of the Caisson Disease," by Howard Van Rensselaer, of Albany.

Forms of Melancholia.—Dr. E. C. Spitzka said there were three states of mental depression classed as melancholia, one being a "sort of hypertrophy of an ordinary fit of the blues;" the second, mental depression from some special morbid fear; the third, the form of melancholia usually described or referred to in the text-books, and often associated with a suicidal tendency. The latter might be accompanied by, but be independent of, symptoms pointing to organic lesions—Argyle-Robinson pupil, absence of tendon reflexes, etc. It should not be forgotten that in the forms of melancholia patients yet manifested original dispositions of character, the choleric being still choleric in his melancholy, etc. He wished to call especial attention to the differential diagnosis between melancholia and that change developing sometimes in persons past fifty, due often to atheromatous changes, and in which the diagnosis is much more serious. The latter patients were not so profoundly depressed and indulged in projects and eccentricities, as the truly melancholic never did.

The prognosis in melancholia was favorable.

Operation for Tumor of the Centrum Ovale.—Dr. Landon Carter Gray then read a paper upon a "Tumor

of the Centrum Ovale," causing motor paralysis and paralysis of the muscular sense, and at the autopsy a round-cell sarcoma about the size of a hickory-nut was found about one-fourth of an inch beneath the cortex, at the junction of the leg and arm centre of the posterior central convolution. The patient was a young man, thirty-eight years of age, who was brought to Dr. Gray from Richmond, Va., by Dr. I. H. White, two weeks after motor paralysis had begun in one lower extremity. As there was a large tumor in Scarpa's triangle, and as an angioma had been removed some time before from the popliteal region, Dr. Gray was led to believe that the symptoms were caused by an intra-cranial tumor. There was motor paralysis of one lower extremity, and paralysis of the muscular sense, slight headache, but no mental symptoms whatsoever. The patient was advised to go home and settle up his affairs, and to have trephining done if he grew worse. Two weeks afterward he was brought to New York, and was found to have a motor paralysis and a paralysis of the muscular sense, also of the upper extremity on the same side with the paralysis that already existed. The patient was gradually becoming comatose. The headache had become very much worse. There were no changes in the optic disk, very slight impairment of the tactile sense, and no motor or sensory paralysis or tremor of any kind other than that mentioned. The patient was operated on by Dr. J. A. Wyeth, but neither by palpation or an exploring needle could the tumor be found. Two days after the operation death ensued, and at the autopsy the tumor was found as above located. Dr. Gray then went over the histories of cases showing the localization of the muscular sense, and showed that this case was the most significant one on record, in the limitation and the rapid growth of the lesion, as indicative of the location of the muscular sense.

Medical Department of the State Library.—Dr. Samuel Ward offered the following resolution, which was adopted: "That the Committee on Legislation be instructed to use every effort in their power to procure legislation establishing and providing means of supporting a medical department of the State Library."

Committee on Nominations.—*Member at large*, Dr. Van Derveer; by districts in numerical order, Drs. Daniel Lewis, E. D. Chipman, W. H. Bailey, Eugene Beach, J. H. Glass, Henry Flood, J. P. Creveling, F. H. Potter.

Two Cases of Traumatic Hysteria.—Dr. Henry Hun read a paper including the report of two cases. In his concluding remarks he said it had been his object to report two cases of well-marked functional nervous disease, belonging to such a clear type of disease as hysteria, which were the result of accidents. Similar cases had been reported by many observers, so that he thought the occurrence of hysteria following and caused by accidents could not be doubted. He thought many of these cases, as well as of those of traumatic neurosis, could be much earlier cured if the patient would enter a special hospital.

The Treatment of Detachment of the Retina.—Dr. David Webster had the past year performed a surgical operation in nine cases of this kind. He thought that this procedure offered some degree of hope, where other measures had caused no improvement.

Dr. Roosa thought the surgical procedure justifiable, but great reliance could not be placed upon a permanent cure.

Dr. Noyes expressed himself even more conservatively.

On the Use of Platinum Instruments in the Extraction of Cataract, etc.—Dr. Gruening, of New York, presented a number of eye instruments, made in part or wholly of platinum, which possessed the special advantage of permitting perfect asepsis by heating to a glow in the spirit-lamp. In devising them he had in view the still further reduction of cases of sepsis following operations.

The Causes of Asthenopia.—Dr. Roosa delivered an abstract of this paper. He denied the existence of perfect refraction. He denied the existence of muscular asthenopia. The common cause was astigmatism. Children squinted because of errors of refraction which they were attempting to overcome, not because there was muscular insufficiency causing asthenopia.

Dr. Noyes took emphatic objection to Dr. Roosa's statement that asthenopia was never caused by muscular insufficiency. He related cases where other measures, including correction of errors of refraction, had failed to give relief from marked nervous trouble, yet cutting the muscles had effected a cure.

Dr. Roosa would explain Dr. Noyes's cases by hypnotic effect of the operation in a neurotic patient.

Migraine and Headache from Eye-strain.—Dr. Peter A. Callan in this paper stated that he had been forced by experience to regard eye-strain as the cause of seventy-five per cent. of all cases of functional headache and migraine.

One Thousand Cases of Ocular Headache, and the Different States of Refraction Connected Therewith.—Dr. W. F. Mittendorf in reading this paper said the views expressed therein were in harmony with those of Dr. Roosa. Most of the thousand cases were seen within two years; most were in private patients. The cause in nearly all cases was astigmatism, often with hypermetropia, less frequently with myopia. In only seven cases was muscular insufficiency the cause of the headache. The treatment was not alone by glasses; he emphasized the importance of gymnastic exercise.

Double Optic Neuritis of Malarial Origin.—Dr. H. W. Ring, of New York, reported the case. He expected to have the diagnosis of malarial origin of the double optic neuritis in this case called in question, yet he thought it was correct.

The Pathology of Appendicitis.—The evening session was devoted to the discussion of appendicitis. The first paper was on pathology, by Dr. Minter, of Buffalo. He described three forms of appendicitis: 1, an adhesive form; 2, with local peritonitis and abscess; 3, universal peritonitis with perforation into the peritoneal cavity. An abscess starting in an appendix must be intra peritoneal, but might perforate in a direction that to open one need not invade the peritoneum.

Dr. A. G. Gerster, of New York, also made some verbal remarks on the subject of the pathology of appendicitis, especially as it had a bearing on operative procedures. As had been stated already by Dr. Minter, the cause of appendicitis was to be sought in stenosis. Yet there were some cases of perforation without stenosis. It might result, for instance, from tubercular ulcers, and from typhoid ulcers. Foreign bodies in the appendix were seldom the cause. The appendix being muscular, had the power to cast these out when not constricted, otherwise inflammation and perforation from this cause would be very common. He believed the most common cause of appendicitis was catarrhal inflammation, which either started in the appendix or caput coli—oftenest, it seemed, in the latter. Thus the cure of mild cases of appendicitis could readily be accounted for. The tumor found in appendicitis was usually located in the right iliac fossa, but the appendix being movable and sometimes long (he had seen it five inches in length), it might be felt at some place quite distant. The adhesion, so to speak, to the surrounding parietes might be small, almost pointed, or broad. The gravity of an operation was much less when the adhesions to the abdominal parietes were such as to permit of the tumor being entered without invading the free peritoneum. He impressed the importance of finding the location of such adhesions in order to operate with greatest safety.

The Indications for Early Laparotomy in Appendicitis.—Dr. Charles McBurney, of New York, read the first paper discussing this subject. Peritonitis in the male was in the vast majority of cases an inflammatory process originating in the appendix. Many of the milder cases of appendicitis recovered, as did also a few of the severer cases.

The author then dwelt on individual symptoms in relation to an early operation—pain, rigidity of the abdominal muscles, vomiting, fever, the pulse, tympanites, tumor. As a rule, rapidly increasing distention was a positively unfavorable symptom. A tumor might not be appreciable the first few days, but as a rule it could be detected by the second or third day; in very mild cases it was absent. There was danger of obscuring the symptoms by too much opium. The patient should be kept at rest. Mild cases could be controlled without operation in twenty-four hours. In somewhat more marked cases there would be fever of 101° to 102° F., decided sensitiveness, more rapid pulse. This might soon come to a standstill, or go on increasing, calling for early operation. The character of some cases would be determined in less than twenty-four hours, indicating an operation. In severe cases the symptoms at an early period were even more marked. To wait seven or more days, it was possible the patient would recover; he was, however, more likely to die. An operation at this period offered much less chance for success than if performed earlier. If there were increasing signs, even in milder cases, at the end of thirty-six hours, he would operate. He had operated in twenty-four cases since May, 1888, all seriously threatening life; all recovered except one. Most were operated upon by the second or third day, only one after a duration of a week.

Dr. W. W. Keen, of Philadelphia, read a paper on the same subject. Every case of perityphlitis should be regarded as primarily an appendicitis, unless the contrary was proven. Clinically he recognized five forms: 1, mild cases, usually ending in resolution without the formation of abscess; 2, perforating appendicitis followed by general peritonitis; 3, limiting abscess, ending in resolution or death within three or four weeks. Occasionally it perforated into the peritoneum. The fourth class followed a chronic course. The fifth class included cases of recurring appendicitis. Only exceptionally was an operation called for in the first class; the contrary was true of the second class. An exploratory operation was comparatively without danger, and should be performed in doubtful cases. In a general way, it could be said an operation should be performed by the second or third day, when there was abdominal pain, most marked in the right iliac fossa, tenderness at McBurney's point, nausea and vomiting, temperature of 101° to 102° F., tumefaction, œdema of the abdominal wall, rigidity of the abdominal muscles.

The Technique of Operative Interference in Appendicitis.—Dr. L. A. Stimson, of New York, read a paper on this subject which cannot be abstracted in few words. Recovery was not impossible with antiseptic precautions and cleanliness, even though the contents of the abscess came in contact with the free peritoneum—a fact which disposed of Dr. Gerster's objection and the necessity which he had claimed for opening at the seat of adhesion and avoidance of exposure of the free peritoneum.

Dr. Francis Bacon, of New Haven, gave his experience in operating in forty cases of pericæcal abscess; all recovered except two. He had seen many cases of what he would now regard as appendicitis, which had ended in resolution. The course which he took in those cases, expectancy, would perhaps be now regarded by Dr. McBurney as indicating unjustifiable temerity.

The Propriety of, and the Indications for, the Resection of the Appendix Vermiformis during the Quiescent Stage of Chronic Relapsing Appendicitis.—The author, Dr. R. F. Weir, felt less conservative regarding exploratory operations and operations for cure than when he wrote a paper a year ago. He had, since then, collected twenty-four cases on which he could base some deductions. There was but one death in the twenty-four, therefore the danger of the operation must be slight. It was impossible, in most cases of recurring appendicitis, to distinguish positively the perforating from the non-perforating form. One should not be guided by the frequency of the attacks alone in deciding whether an operation should be undertaken, but also by their severity and duration. The risk of the operation might be greater than that of the disease, in which case it would not be justifiable. Each case must be a guide unto itself.

The Relation of the Physician and Surgeon in the Care of Cases of Appendicitis.—Dr. Albert Van Derveer, of Albany, pointed out in this paper the necessity for an early operation in many cases, if life was to be saved, consequently the physician should become expert in recognizing symptoms of appendicitis, and call the surgeon in consultation at once. The latter must be responsible for the results if an operation were undertaken.

There was further general discussion on appendicitis, by Dr. Montgomery, of Philadelphia; Dr. Davis, of Alabama, and others.

Second Day, Wednesday, February 4th.

Discussion on Pelvic Inflammation in Women.—Dr. A. F. Currier read an introductory paper on this subject. In pelvic inflammation in women there was pain, swelling, and elevation of the temperature, as in inflammation elsewhere. The important point was to determine the cause, what tissue was involved, to what extent, what was the best form of treatment. These points would be discussed by others.

Pathology.—Dr. Raymond, of Brooklyn, in a paper on the pathology of pelvic inflammation, expressed the opinion that pelvic cellulitis, while rare as an independent entity, did sometimes occur. It could be caused by contusion, by transmission of infection from the uterus through the vessels, or by apoplexy. It might end in resolution or abscess. The pus might burrow, find an outlet, and complete recovery take place even without treatment. Chronic cellulitis bore the same relation to the acute as ashes did to fire. A second class of cases included pelvic peritonitis, which might arise in connection with constitutional disease, sepsis, rupture of a Graafian follicle, exposure; it might be circumscribed or involve the whole pelvic peritoneum. Pus might form, especially in virulent septic cases. A third division included salpingitis, which, however, seldom occurred alone. The great majority of these cases were due to endometritis, either catarrhal or septic. Ovaritis constituted another class of the pelvic inflammations. Clinically he recognized acute ovaritis and degenerative or chronic ovaritis. If in any of these forms the inflammation subsided before pus formed, he thought there would be less trouble from adhesions if an operation were performed. Where pus existed laparotomy was called for, or evacuation through, say, the vagina.

Dr. W. Gill Wylie, of New York, also read a paper on the pathology of pelvic inflammation, in which he stated that his views had not changed since five years ago, when he related some cases and said that, nine times out of ten, so-called cellulitis was due to salpingitis, or inflammation which had extended from the uterus to the tubes. He would now state this proportion as 99 to 1. Pelvic cellulitis had been found by him only as a result of diseased appendages, now and then it followed immediately on sepsis after labor. Retroversion with adhesions meant really salpingitis with adhesions. The cause of sepsis producing tubal disease was nearly always poison introduced at labor or by the operator. Gonorrhœa was a much less frequent cause than was generally supposed. Tamponing the vagina or using tents often caused septic matter to be forced up into the tubes.

Syphilis and tuberculosis were exceptional causes.

Radical Treatment.—Dr. L. S. McMurtry, of Louisville, stated, in discussing this phase of the subject, that pelvic cellulitis was so rare that it might be passed on this occasion. On the other hand, pelvic peritonitis was common and dangerous. In most cases it could easily be traced to infection. The only treatment which would cure suppurative disease was surgical removal.

The authors of other papers on this subject were absent.

Proposed Law on Embalming.—Dr. Suiter read a paper relating to the subject of embalming by undertakers and its legal bearings, and offered a resolution approving of a bill to be presented to the Legislature, regulating this matter. It was adopted. The Society also approved, on motion of Dr. Jacobi, of the proposed bill to appropriate $450,000 by the State for care of the insane.

Catarrh and its Cure.—Dr. O. B. Douglas, of New York, in this paper, said that cure would depend upon removal of the cause. The usual cause was trauma, or, rather, deformities resulting more or less remotely therefrom. Where mucous surfaces were abnormally in contact with each other, catarrh would result, and would be cured only by removal of the cause of the unnatural contact.

Dr. Jarvis strongly approved of the statement that a cure of catarrh could only be effected by curing the condition on which the symptom depended.

The Treatment of Posterior Displacements by the Utero vaginal Suture.—Dr. H. J. Boldt described this operation and gave results. He had performed it himself nine times, and, considering the time which had expired, the results had been satisfactory. He knew of no deaths following it, and could give statistics of one hundred and fifty cases. With present improvements and cautions, there was no danger of injury to the bladder or intestines. Seven patients had been known afterward to bear children.

Drs. Currier and Wylie strongly opposed this operation as being dangerous, and not as promising in success as other more surgical measures.

The Emotional Element in the Puerperal Period.—Dr. Adams H. Wright, of Toronto, in this paper, related seven cases in which the emotional element, alone or partly, caused fever in the lying in state. In two the fever reached, in an hour or two after disagreement with a nurse, 104.5° F., and fell within a day to normal after the nurse had been discharged. He thought physicians were becoming too much disposed to look upon the human system as a mere machine.

The Treatment of Injuries to the Floor of the Vagina.—Dr. Horace T. Hanks, of New York, enforced in this paper the necessity for passing the sutures deeply, and taking up the injured fibres of the levator ani muscle.

Dr. Boldt agreed with this injunction, and Dr. Waldo impressed the need of an early operation, though secondary, before atrophy of the muscles had gone to that degree that restoration was impossible.

Dr. Lewi here read the report of the Committee on Legislation, which referred to matter familiar to the readers of the Medical Record.

An Inquiry into Our Present Knowledge of the Progress of Myomatous Tumors.—Dr. J. F. W. Ross disapproved of attempts to use electricity for curative purposes, as it was inferior to an operation, and was not without danger. He considered electrical treatment of limited service, and only applicable in cases of hemorrhage in which other operative procedures were not permitted. He advocated the removal of ovaries and tubes, together with hysterectomy, in proper cases.

Dr. Van Derveer, strongly condemned palliative, including electrical, treatment, until the patient became greatly reduced by hemorrhages, etc. He favored radical treatment where the symptoms demanded.

Dr. Wylie found electricity effective only when used as a caustic, and this was objectionable, as it caused a scar and laid the basis for future nervous symptoms.

Dr. Currier spoke more favorably of electricity.

The Medical Examination Bill Approved.—On motion of Dr. Daniel Lewis, the Society adopted a resolution disapproving of any change being made in the Medical Examiners bill until it shall have a fair trial.

Discussion on Pulmonary Tuberculosis.—Dr. H. R. Hopkins, of Buffalo, opened the discussion with a paper on the History. He divided the history into two periods, first, from Hippocrates to Sylvius—the period of the art of medicine; second, from the latter date to that of Koch, which he called the period of the science of medicine. He expressed much hope from the present period, especially in the line being pursued by Koch.

Etiology and Pathology.—Dr. Heneage Gibbes, of Ann Arbor, Mich., in this paper spoke of the pathology under two divisions: first, inflammatory, consisting of pneumonic phthisis and the inflammatory form of acute miliary tuberculosis; second, tubercular, consisting of pulmonary tuberculosis and the tubercular form of acute miliary tuberculosis. The etiology of pneumonic phthisis seemed to be as easy of explanation as any other form of inflammation. The process could be explained without supposing there was a specific micro-organism, and the bacillus, in fact, was absent until caseation had set in. The etiology of the tubercular form was more difficult of study, but, since the bacillus tuberculosis might be absent from the commencement, he claimed it was not the cause. Inoculation with this would produce a lesion in susceptible animals, but he denied emphatically that it was similar histologically to the lesions found in acute miliary tuberculosis. The difficulty, however, consisted in getting a *pure* culture of the tubercle bacilli free from morbid products of the lungs. It was to some morbid product or chemical agent that he and Dr. Shurley, who had experimented with him, attributed the disease, and not to the bacillus. By use of a preparation of chloride of gold he had been enabled to render culture of the tubercle bacilli perfectly innocuous to animals in whom they were injected.

Treatment, Including Prophylaxis as Related to Climate.—Dr. Samuel B. Ward, of Albany, pointed out the advantages in phthisis of a climate which was relatively free from humidity, light atmospheric pressure (within certain limits), purity of air, equability of temperature, presence of sunshine. He had found Saranac Lake, N. Y., a desirable place for many consumptives.

Treatment as Related to Therapeutics.—Dr. E. L. Shurley, of Detroit, read this paper, which was founded on views similar to those expressed of the pathology and etiology by Dr. Gibbes. Clinically and theoretically, it seemed unreasonable to attribute so many forms of disease to one cause as had been attributed to the tubercle bacillus. He thought there was some agent at work of a chemical nature, which he had tried to neutralize by injections of certain agents. Chemically pure iodine, and chloride of gold, used in small amount hypodermically, had produced almost uniformly amelioration of the symptoms, in proportion to the small extent of the disease.

Manifestation of Tuberculosis in the Upper Air-tract.—Dr. John O. Roe, of Rochester, treated of this phase of the subject. There were two forms of lesions, lupus and tuberculosis, produced here by the bacillus tuberculosis. The first usually produced rapid destruction, the latter slower destruction. The latter might be primary, or secondary to pulmonary tuberculosis. When primary it should be removed; when secondary one might be able only to palliate symptoms, as by iodine, but never use irritants. Cocaine made an operation simple. Remarkable results had been obtained in some cases of laryngeal tuberculosis from injections of Koch's lymph.

Dr. Herman Knapp showed photographs of tuberculosis of the eye from the incipient to the terminal stage, the case ending in cure and a cicatrix, in a rabbit.

Lobar Pneumonia with the Production of Connective Tissue in the Air Spaces.—Dr. Francis Delafield, of New York, expressed the belief in this paper that a lobar pneumonia with the production of new connective tissue was from the first a special form of inflammation of the lung. He had seen twelve cases which seemed to belong to this group. Such an inflammation lasted longer, and was more likely to become chronic, than cases with simple exudative inflammation. His cases illustrated at autopsy three stages of the disease according to anatomical

changes. The clinical history was also somewhat different from the simple exudative form. It was reasonable to believe recovery was possible.

The Surgical Treatment of Ectopic Gestation.—Dr. Charles S. Read, of Cincinnati, read the paper. He advocated excision of the mass in preference to other methods, or electricity.

Apparent shock from rupture was likely to be due to continuation of hemorrhage, which he believed was nearly always into the peritoneum, and thought it questionable whether one should wait for the patient to rally from the apparent shock.

Papers on Experience with Koch's Lymph.—They were by Drs. A. Jacobi, H. N. Heineman, and W. C. Bailey, of New York, and remarks by Dr. Fox, Dr. Bacon, of New Haven, and Dr. H. R. Hopkins. Most of the experience narrated has appeared in the Medical Record. The speakers generally expressed the view that this marked an important era in curative measures.

For State Examiners.—Committee recommended to the Regents for State Examiners—Drs. W. C. Wey, B. F. Sherman, W. W. Potter, W. R. Ely, George F. Shrady, J. P. Creveling, L. S. Pilcher, Edward B. Angell, George R. Fowler, H. D. V. Pratt, C. L. Dana, Eugene Beach, V. P. Gibney, M. J. Lewi.

The President's Address.—Dr. W. W. Potter chose for his address, delivered before a mixed audience, a subject bearing on the prevention of disease in women. Special attention should be given to the development of girls from ten to fifteen or twenty, the period of change into womanhood. At present this time was devoted to what we called intellectual development. It was too much at the expense of the physical. Faulty methods also applied to dress, the French heel, etc., were condemned. During the catamenial period less school-work should be exacted. The brain and ovaries could not develop at the same time without a proper nervous equilibrium was maintained. Otherwise the one or the other would give way. Usually it was first the ovaries. The pangs of maternity were increased by faulty educational methods far beyond the intent of the Creator expressed in the decree "in sorrow and suffering shalt thou bring forth children." Many of the local disorders in women did not constitute the essential disease, but were simply the expression of a general neurosis brought on by faulty methods during growth. Four hours school work were sufficient between the ages of twelve and sixteen. The mother should supervise the menstrual period. Girls should eat heartily of plain food. Clothes should be warm and supported from the shoulder. Girls should not be compelled to ascend more than two flights of stairs at school.

Third Day, Thursday, February 5th.

On the Causes of Eczema.—Dr. Bulkley recognized different causes for eczema, but back of it lay a systematic condition which must receive more attention even than the local condition in treatment.

Treasurer's Report.—Dr. Porter read his report, which showed: Total receipts, $2,894; expenditures, $2,238; balance, $656.

Enlarging the Transactions.—The Committee on Publication was granted power to enlarge the volume of Transactions.

The Action of Trypsin, Pancreatin, and Pepsin upon Sloughs, Coagula, and Mucus.—Dr. R. T. Morris had found the digestive ferments effectual in digesting coagula, etc., in old abscesses. The cavity was afterward cleansed with water and sterilized by peroxide of hydrogen; pepsin was best.

The Treatment of Gall-stones.—Dr. W. W. Seymour read the paper on the above subject, in which he advocated for obstinate cases operative interference. The views expressed were in substance those published in his recent paper on the subject in the Medical Record.

Incision not Excision.—Dr. Samuel Lloyd read a paper, a review of operative surgery of the spine. Report of a successful case.

Report of the Nominating Committee. - For *President*, Dr. Walter Suiter; *Vice-president*, Dr. W. W Crandall; *Secretary*, Dr. F. T. Curtis; *Treasurer*, Dr. C. H. Porter. *Committee on Arrangements:* Drs. Ward, Bendell, and Partridge. *Committee on By-laws:* Drs. Pratt, Simmons, and Curtis. *Committee on Hygiene:* Drs. Johnson, Bell, Stiles, Babcock, Balch, Bailey, and Clark. *Committee on Legislation:* Drs. Roosa, Lewis, Lewin. *Committee on Ethics:* Drs. Jacobi, Matheson, and Hopkins. *Committee on Prize Essays:* Drs. Fox, Grandin, W. W. Potter. *Committee on Publication*: Drs. Curtis, Douglas, Persons, Porter. *Honorary Members:* Drs. H. C. Wood, W. H. Hingston, Joseph Price, W. H. Taylor, E. E. Montgomery, J. N. Hyde. *Eligible to Honorary Membership:* Drs. L. S. McMurtry, C. A. L. Reed, W. E. B. Davis, A. H. Wright, and J. F. W. Ross. All of whom were duly elected.

Other papers were read by title.

THE NEW YORK PATHOLOGICAL SOCIETY

Stated Meeting, November 26, 1890.

J. West Roosevelt, M.D., President, in the Chair.

Melanotic Myeloma.—Dr. Charles Heitzman presented such a tumor, removed from the right malar region, together with the following history:

A lady, fifty years of age, of healthy appearance, presented herself on November 21st, with a dark, nearly black, discoloration of the skin, about one and a half inch in diameter in this region, reaching to the outer canthus of the eye, and extending downward and outward. The pigmentation appeared mottled, owing to variations in color from gray to nearly black. This spot had developed within the last six years. In its centre was a tumor the size of a split pea, likewise pigmented, of a rather soft consistency. It caused no pain, and had grown within the last six or eight weeks from a minute nodule to its present size. The patient said that the pigmented area had assumed its mottled appearance only since the tumor had begun to grow. The diagnosis was, malignant melanotic tumor. The tumor was excised with a pair of curved scissors, and the hemorrhage checked by liquor of iron. To the naked eye, the whole tumor appeared of a slate color. After hardening in chromic acid solution, one per cent., it was examined microscopically, and its structure found to be that of a net-celled sarcoma of Virchow. Large, spindle shaped, mostly nucleated, protoplasmic bodies produce comparatively coarse network by freely anastomosing with one another. Within the spindles are found a moderate amount of dark brown and gray clusters of pigment of varying sizes. This proves the correctness of the clinical diagnosis. At the same time an extremely unfavorable prognosis must be made, since it is known that wherever such melanotic tumors appear, rapid local growth, dissemination in the skin, and secondary formation of myeloma in internal organs are to be expected, in spite of all attempts at eradication. Within two years, such cases terminate fatally. Spontaneous involution is extremely rare, and possible only when the pigmentation is diffuse, and pigment clusters are lacking.

Dr. H. N. Heineman said that perhaps Dr. Heitzman might recall the case of a young man under twenty-eight years of age, which had been presented to the Society about ten years ago. A tumor caused marked protrusion of the eye, and melano-sarcomatous growths developed in the skin, lungs, brain, and elsewhere, until finally the entire body assumed a dark color. The patient died in less than eighteen months after the original injury. It was interesting to note that the tumor began on the face. In this particular case, the choroid might be considered the source of the pigmentation, but this would not explain its origin in tumors situated in other parts of the body,

except perhaps those located in the deeper layers of the skin.

Dr. Heitzman said that he did not recall the case. He had confined his remarks to cases within his own personal experience. Some years ago his son had prepared and published an article on the subject of the source of the pigmentation. In one case, the tumor of the choroid grew into the vitreous body, thus allowing of ocular demonstration of the fact that the pigment in that instance arose from what the speaker had described in 1873 as "hæmatoblasts." These hæmatoblasts are the forerunners of the red blood-corpuscles, and evidently contain hæmoglobin, from which the pigment is probably developed. In all the cases which his son had examined, similar features were observed, and in the specimens presented this evening close examination would show the peculiar yellow hæmatoblasts—small glistening lumps of high refractive power, evidently containing hæmoglobin. Two varieties of pigment have been found, and these two varieties seem to be at times combined; for, in many instances, the pigmentation of the skin is the primary phenomenon. He had known one gentleman to have black spots on the extremities for years, but finally nodules appeared in other places, and shortly afterward he died. This case would indicate that the pigmentation was a presage of the tumor itself. These pigmented growths far exceeded in malignancy cancer, or even white sarcoma.

In answer to a question from the President, he said that he did not consider the pigmentation to be of blood origin, but formed from the spindle cells. Either the organ in which the tumor grows is pigmented, or else the skin becomes pigmented, as, for instance, in a mole. Such a spot is ordinarily without significance, yet long afterward, if a tumor form here as a result of some slight irritation, melano-sarcoma would probably develop.

The President said that in one case of this kind which he had seen, the trouble began in the right parotid region. Four or five times the tumor was excised, and when he last saw the patient there were a number of these growths in the skin of the abdomen, and the liver was greatly increased in size, and contained hard, rough masses. All of these tumors which he had examined were melanotic. Within a period of fifteen months the patient had hæmatemesis and other symptoms of malignant disease of the stomach.

Abscess of the Temporo-sphenoidal Lobe, Secondary to Otitis Media.—Dr. C. N. Dowd presented a specimen of this condition, and dwelt upon the relations existing between the clinical history and the pathological findings as illustrated in his own case, and in several others which had been published. In the specimen presented the brain was of the normal size, and the dura mater normal in appearance. The pia mater was somewhat lacking in lustre, especially at the base of the brain. Within the left temporo-sphenoidal lobe was an abscess about the size of a hen's egg, having no external opening. The pia mater was softened and thickened where it lay upon the petrous portion of the temporal bone. There was normal brain-tissue, one-half to three-quarters of an inch in thickness between the pia and the abscess, over nearly the entire surface of the lobe. The walls of the abscess were necrotic and of a dark green color, and its cavity was filled with thin, greenish pus. The petrous portion of the temporal bone was broken down and infiltrated with pus. Microscopical examination showed much broken-down material and an infiltration of the abscess-walls with leucocytes. Between the abscess-wall and the pia mater was normal brain-tissue. At the lower portion of the lobe the pia showed exudative inflammation, some of the folds in the sulci extending to the areas of inflammation within. Sections taken from the crus cerebri showed a similar condition, while those taken from the vertex gave no evidence of inflammation. Sections of the dura mater taken from beneath the left parietal bone were normal.

The patient from whom this specimen was taken was a well-nourished boy of ten years, who first came under hospital observation on August 28, 1890. When about three years of age he had had scarlatina, but since then he had enjoyed good health, with the exception of several attacks of earache and otorrhœa from the left ear during the last three or four years. For about a week preceding his admission he had suffered from headache and earache, hot and cold sensations, and evening delirium, yet had played around until the morning of August 28th, when he had vomiting, frontal headache, and fever, but no chill. When seen that afternoon, he was prostrated so that he could hardly walk; there was marked rigidity of the neck, and the head was held extended. On lying down he quickly flexed his legs and arms, and seemed most comfortable in that position. The pupils were equal and reacted to light. There was slight nystagmus, but no ptosis or photophobia. No disturbance of sensation or of the power of motion was noted, and there was a tendency to convulsions. Pulse, 72; respirations, 28; temperature, 103.8° F. The left tympanum was perforated, and there was a slight purulent discharge, but there was no tenderness over the mastoid process. Physical examination of the chest and abdomen revealed nothing abnormal. The urine was alkaline, specific gravity, 1.016, and a trace of albumin. Phosphates were visible under the microscope.

August 29th.—Patient delirious all last night, and had five general convulsions, and several attacks of opisthotonos. This morning he is greatly exhausted, face cyanotic, marked nystagmus. During the day he was rational and took nourishment, but in the evening he again became delirious, crying out in a shrill voice, and becoming so excited as to require to be confined to bed by force.

August 30th.—He was quieter during the latter part of the night, and there were no more convulsions or opisthotonos. The ophthalmoscope showed no change in the optic disks. Bowels were costive, but responded to cathartics.

September 1st.—Slight tenderness over the left mastoid process. He steadily failed, and died on September 3d. Stupor came on two days before this, and gradually deepened into coma. On the first two days of this illness the temperature was 103.8° F.; pulse, 75, and respirations, about 30; but after that the temperature ranged between 99° and 101° F., excepting those sudden variations which are so often present when there is an accumulation of pus. He had the typically slow pulse of meningitis.

It is very remarkable that so extensive a lesion should have given rise to so few symptoms, yet the necrotic condition of the abscess-walls indicated that the abscess had existed for a long time. It is also surprising that the boy should have appeared so healthy and vigorous up to August 20th. It is true that after he came into the hospital there were symptoms indicative of meningitis and of the accumulation of pus, but none which pointed definitely to involvement of brain-tissue.

The location of the abscess explains the absence of marked symptoms from involvement of the cerebral centres; yet the centres of smell and hearing are believed to be situated in the temporo-sphenoidal lobe, that for smell being in the uncinate convolution of the median surface near the apex of the lobe, and that for hearing in the posterior half of the highest temporo-sphenoidal convolution. The history in this case did not indicate that there was any impairment of the sense of smell or of hearing, and it is quite possible that the other side of the brain may have assumed these functions.

It is evident that in cerebral abscess we must not expect definite symptoms from the involvement of the centres, unless the motor tract is implicated, and Gowers states in his work that he is "aware of no case in which the indications of cerebral localization have alone guided the operator successfully." The importance of the local symptoms would, of course, be increased in cases of traumatism or of long-standing inflammation.

In some cases, though not in this, there is evidence of involvement of the cranial nerves or their sheaths, as when choked disk is observed.

These abscesses usually find their way to the surface, and cause a fatal meningitis, or they cause death by rupturing into the ventricles. The probability of their draining through the ear is very remote.

Von Bergmann has collected eight cases in which the diagnosis was made and the abscess opened, and three of these recovered. In one of the successful cases, otorrhœa had existed for eleven years, and acute symptoms with headache, depression, and slight double optic neuritis for about three weeks. The cleansing of the middle ear after opening the mastoid cells gave rise to nystagmus, and the patient had persistent fever, and a chill. A diagnosis of cerebral abscess was made, and an opening one and one-half inch posterior to the external auditory meatus, and one and one-half inch above Reid's base line was made, a trocar inserted, and the abscess drained. The chief symptoms complained of in this series were headache over the affected side, and great pain on percussing this area, nausea and vomiting, and either somnolence or complete loss of consciousness.

In another case, operated by Greenfield, there was a history of left otorrhœa and the development of the left optic neuritis with paralysis of the third, fourth, and sixth nerves. It was thought that there was an abscess of the temporo-sphenoidal lobe, with an extension of the inflammation from the meninges to the nerves. An opening was made about one inch above the zygoma and one and one-fourth inch behind the external angular process, and the abscess drained.

In studying the reported cases, it is noticeable that in the few cases where the diagnosis has been made, there has been, almost without exception, involvement of the cranial nerves or the motor centres. The symptoms of meningitis and those of pus-formation, associated with otorrhœa, have been of importance, but they have not furnished sufficient ground for diagnosticating and locating an abscess.

It is also to be remembered that in about one-fourth of the cases of brain abscess due to otitis media the abscess is not in the temporo sphenoidal lobe, but in the cerebellum, pons, or crura cerebri, and this still further increases the difficulties of the subject. Some aid may be derived from the fact that about one-half of all cases of abscess of the brain are secondary to otitis media.

When the symptoms are urgent, the opening of the mastoid cells is certainly to be recommended. When there is no abscess this may relieve the middle ear by giving a free exit to the pus, and thus preventing further extension of the inflammation; when an abscess is present, such a procedure may furnish ground for a diagnosis by exclusion, as in the case already quoted. It is an operation which is easily performed, and is almost free from danger.

Dr. Heitzman said that it was easy to understand that foci of suppuration might be established by the transmission of staphylococci from other centres of suppuration; but in a case presented to the Society, about sixteen years ago, by Dr. J. Lewis Smith, a child about one year of age, was found to have a small abscess lodged in the centre of the left hemisphere in the medullary substance, in the neighborhood of the left ventricle. The abscess finally burst into the left ventricle and the child died. The brain is in Dr. Heitzman's collection.

Those who accept the theory that there is no suppuration without the presence of one or more of the varieties of staphylococcus, believe that these organisms are circulating in the blood, and that when a traumatism occurs the accompanying stasis in the blood-vessels causes their lodgement at the seat of injury. It is on this theory that they have endeavored to explain the formation of pus in the very centre of the shafts of bones, as occurs in osteomyelitis. Others believe with Strycker, that suppuration is not due to a pouring out of colorless blood-corpuscles, but to the breaking down of inflamed tissue. If the inflammation become plastic around the abscess, new blood-vessels and connective tissue are formed, giving rise to the so called pyogenic membrane. The migration theory of Cohnheim had lost ground lately in Germany.

Dr. J. S. Elv thought with Dr. Heitzman, that the most interesting pathological question in connection with Dr. Dowd's paper was, how these organisms, to which we must now attribute suppuration, found their way from the middle ear into the interior of the brain, without any evidence of direct extension of the process. We are accustomed to think of three channels of distribution of these organisms through the body, *i.e.*, the arteries, the veins, and the lymphatics. It was well known that there are no arteries or veins passing directly through the dura mater and pia into the brain at the part of the brain already cited as being the seat of the abscess. The nearest artery to the tympanic cavity of any size is the tympanic branch of the internal carotid artery; hence, for a poison to be distributed by it, it would be necessary for it to pass against the blood-current to the internal carotid, and thence be distributed by the internal carotid and middle cerebral arteries to the upper portion of the temporal lobe, which is supplied by this artery. The lower portion of this lobe is the more common seat of abscesses, and it derives its blood-supply from the posterior cerebral artery behind the posterior communicating artery of the circle of Willis, which connects this artery with the internal carotid. Hence, in order that anything should be carried to the temporo-sphenoidal lobe by the posterior cerebral artery through the tympanic branch, it must pass through the internal carotid artery, and through the posterior communicating branch, which is absurd, as it is against the blood current. For similar reasons, it is out of the question to suppose that extension of the process could take place through the middle meningeal artery; and in the same way, the veins can be excluded. We are therefore forced to conclude that the lymphatics are the only possible means of transmission. A fine net-work of lymphatics perforate the surface of both dura mater and pia, so that it is not difficult to believe that poison might be very readily transmitted through the dura mater into the arachnoid cavity, and that the lymphatics in the pia mater might again take up the poison and transmit it along the vessels through the sulci into the brain substance. This would also explain the frequency with which abscesses occur in the lower portion of the temporo-sphenoidal lobe. It is well known that micro-organisms often pass into deeper tissues without affecting those through which they have passed. In the case cited by Dr. Heitzman, it is quite possible that the circulation might have carried the poison from the middle cerebral artery to the basal ganglia.

The President said that the lymphatics seemed to be considered a scapegoat for all objectionable things in the human body. The lymphatics were of course an under-drainage system of the body at large; but the direction of the lymph current was not known, and he saw no reason for supposing that the lymphatics on one side of the dura mater should empty micro-organisms into the cerebro-spinal cavity, and the lymphatics on the other side should take them up and dispose of them where they would do most harm. Speaking of the condition of the sense of hearing in these cases of abscess, he would say that in two cases which he had observed, the hearing was unimpaired, although in both cases the drum was perforated by large openings, and the middle ear was practically destroyed. In a case of otitis media which he had seen two or three years ago in his service at Bellevue Hospital, the patient became stupid, and there was intense pain and tenderness over the left mastoid region. Dr. Hartley operated, but found no disease of the mastoid cells or of the veins. The patient died forty-eight hours afterward, and the autopsy showed that the cerebellum on the affected side was almost entirely destroyed. There was no disease of the temporal lobes.

THE NEW YORK ACADEMY OF MEDICINE.

SECTION OF GENERAL MEDICINE.

FRANCIS DELAFIELD, M.D., CHAIRMAN.

Stated Meeting, January 20, 1891.

Election of Officers.—DR. FRANCIS DELAFIELD was re-elected Chairman, and DR. CHARLES E. QUIMBY, Secretary, of the section for the ensuing year.

Phthisis, its Classification, Early Diagnosis, and Relations to Chronic Pneumonia.—DR. R. C. M PAGE read a paper on this subject. Since the recent discovery of Koch for the treatment of tuberculosis in general, he said, it was perhaps more important than ever that we should have a clear definition of the disease so far as it affected the lungs, as well as a convenient and proper classification of its various forms, its relation to certain similar affections, and, above all, the best means for an early diagnosis.

The term phthisis, as now generally understood, signified pulmonary tuberculosis, the germ of which is Koch's tubercle bacillus, and which is infectious under certain conditions. The two grand divisions of the disease were the acute and chronic varieties.

1. Acute phthisis occurred when the progress of the disease was rapid. It might appear to commence as a lobar pneumonia, but its true nature soon became evident. Instead of resolution taking place, as usual, there are signs of softening, followed by excavation, rapid emaciation, and death in the course of a few weeks. Various names had been given to such cases; but inasmuch as phthisis was always and necessarily a tubercular disease, it was sufficient to characterize them as acute pneumonic phthisis.

Acute phthisis might also be a part of that form of the disease known as miliary, general, or disseminated tuberculosis, which affects various organs and tissues throughout the body simultaneously. The physical signs of the pulmonary disease in such cases were simply those of bronchitis; the tubercles being disseminated throughout the lungs. This disease was nearly always secondary to some pre existing tubercular lesion, from which bacilli in large numbers were absorbed into the circulation. The tubercle bacilli did not proliferate readily in the circulating blood, but might be conveyed by it, to a limited extent, even in ordinary cases of chronic phthisis, especially to such organs as the liver, kidneys, spleen, and cerebral meninges, in which the local circulation favored their lodgement. In general miliary tuberculosis, however, the bacilli entered the blood in large numbers, either through the lymphatics—especially the bronchial glands—or by unoccluded veins. All the varieties of acute phthisis mentioned by authors might be reduced to the two principal forms given, acute pneumonic phthisis and acute disseminated phthisis.

2. Chronic phthisis, likewise, had been described under a number of different forms; but these also might all be reduced to two, according to the tissues chiefly involved, namely, catarrhal and fibroid. These two varieties were not always distinctly separate, but might, and often did, exist together in various proportions. Catarrhal phthisis was that chronic form of the disease most commonly met with, and that which usually appeared first at the top of the lungs. The reasons given for its affecting the apices first were as follows: 1. These parts are the most liable to injury from exposure or strain from coughing or lifting, and, according to Green, injury to the vessels from imperfect circulation and stagnation of blood—conditions tending to produce frequent exudations favorable to the lodgement of bacilli. 2. There is less respiratory motion, with consequent imperfect ventilation and less tendency to the absorption of exudations and disturbance of bacilli. Beginning in the bronchioles, which become plugged with an inflammatory exudation, and usually limited to a circumscribed area, the disease extended down into the air-cells; resembling in this respect catarrhal or lobular pneumonia. It was in fact a tuberculous lobular pneumonia, and this was one of the names by which it was known.

The walls of the bronchioles became infiltrated with mucocytes and epithelioid cells, as in ordinary inflammation, and in severe cases fibrin and even blood are found. But, besides these, there were tubercles which characterized the disease, distinguishing tubercular inflammations from all others. Having given a description of the tubercle reduced to its ultimate elements, Dr. Page said that it was not, according to Williams, to be regarded as an adventitious growth, but simply a hyperplasia of normal tissue caused by tubercle bacilli which had been introduced from without—usually by means of inhalation—and found lodgement in a favorable soil. These tubercles are also primarily similar, if not identical, in all forms of the disease and in whatever locality found; differing chiefly in color and consistency according to their age and the changes they had undergone. So-called scrofula, it was now well known, was nothing more than tuberculosis of the lymphatics.

As the disease p ogressed there soon occurred caseous metamorphosis of the tubercles and other products mentioned, together with necrosis of the delicate tissues involved; resolution being impossible. Softening of these caseous materials led to the formation of cavities, partly by absorption, but chiefly by expulsion in coughing. The bacilli were found chiefly in the softened contents and on the walls of the cavities, but might also exist in all the affected tissues. In some cases the cavities became closed, owing to arrest of the disease, and a cicatrix was left. In others, becoming firmly enclosed by connective tissue, their contents cretefied. In the majority of cases, however, as was too well known, the disease progressed and the patient died. In speaking of the mode of extension in this form of phthisis he said that the vessels were usually occluded in the ulcerative process, so that it could not spread by absorption into the blood, except under the circumstances before mentioned. It had no predilection for the lymphatics, like fibroid phthisis; but it extended along the air-passages from one point to another, as well as by imperfectly expelled virus being sucked back, during inhalation, into parts as yet unaffected.

Intestinal ulcerations are also likely to be formed by the swallowing of virus, and they occurred in about one-half the number of cases, both of catarrhal and fibroid phthisis. Owing to the presence of gastric juice, ulceration of the stomach did not occur except in extreme cases of emaciation; the virus more readily finding a lodgement in the region of the ileo-cæcal value, the larger intestine, and sigmoid flexure. The mesenteric glands and peritoneum then became affected secondarily by absorption. Laryngeal phthisis, spoken of by some authors, was simply tuberculous laryngitis, which was probably always coincident with tuberculosis of the lungs.

The second form of the chronic disease, fibroid phthisis, according to Coats, also began in the bronchioles, but it extended, not by the air passages, but along the lymphatics to the peribronchial, interlobular, and sub pleural connective tissue. In very rare instances, extension in reverse order might occur from a tuberculous pleuritis. In other words, fibroid phthisis was a tuberculous interstitial pneumonia, and, like chronic interstitial pneumonia, it led to bronchiectasis and shrinkage. Very few bacilli, sometimes none at all, were to be found in the lung tissue; they chiefly existing in the sputa and on the walls of the bronchiectatic cavities. As to the relation between chronic interstitial pneumonia and fibroid phthisis, Dr. Page said that before the discovery of the Koch bacillus they were regarded as the same disease. After this, however, the two diseases were separated, and great care was taken to differentiate them; but during the recent Berlin Congress they were again considered to be the same disease—always a tubercular one. Even in cases of potter's lung, knife-grinder's consumption, and other forms of pneumono-koniosis the tubercle bacillus, according to Williams, was nearly always found.

In chronic phthisis of either form, the prognosis depended much on an early diagnosis. As to the earliest signs by which it could be recognized, if the top of the left lung were affected it was much easier to make an early diagnosis than if the trouble were on the right side, since in health there existed on the right side exaggerated fremitus and pectorophony, as well as slight dulness on percussion and rude respiration—four signs of incomplete consolidation met with in incipient phthisis, if occurring on the left side. In addition to these, therefore, some localized adventitious sound was necessary, and as chronic phthisis of either form usually began as a localized tuberculous capillary bronchitis, the first adventitious sound usually heard was the subcrepitant râle. Any localized adventitious sound in a suspicious case, would, however, aid in the diagnosis of phthisis. Frequency of the pulse and loss of appetite were among the earliest general symptoms. Of course, hæmoptysis, if it were not explained by the presence of heart disease or other cause, would be almost conclusive.

The question naturally arose, shall we rely only upon finding the bacillus? Of course, if the bacillus was found, it would be conclusive. But did we find it before the subcrepitant râle was heard, and were we to wait until it was found before we were justified in resorting to improved methods of treatment, involving perhaps the sending of the patient away from his business? The cough of chronic phthisis was at first dry and hacking. Expectoration was scant, and what sputum there was did not contain bacilli, except in very exceptional cases, because they were not yet liberated. Examination of the larynx had been claimed as the best method of arriving at an early diagnosis; but, as already stated, primary tuberculous laryngitis was rare, and by the time it was apparent the disease in the lungs had already been recognized.

In speaking of Koch's lymph, Dr. Page said, in conclusion, that time had not yet elapsed sufficient to determine the real value of this reported discovery. But even if all that could be claimed for it should be true, the importance of an early diagnosis and the prompt application of the remedy, was evident; for when loss of important tissue and disease of other organs had occurred, through ulceration and other processes, their still remained pressing considerations regarding treatment, even after the bacillus had been driven from the field.

Tuberculosis in Children; Primary Infection in the Bronchial Lymph Nodes.—Dr. W. P. Northrup read a paper on this subject. He said that the object of the paper was to illustrate and strengthen the theory put forth in the title. In the New York Foundling Asylum the records of one hundred and twenty-five post-mortems on cases of general tuberculosis, in which the details were sufficiently clear to classify them carefully for the purposes of the paper, furnished the following analysis:

1. Thirty four indeterminate cases, in which the lesions were so extensive, involving the organs of the thoracic and somatic cavities, bronchial lymph nodes, and mesenteric as well, that the point of primary infection could not be determined.

2. Twenty cases of bronchial node infection; cheesy masses in lungs; general tuberculosis.

3. Forty-two cases in which only cheesy masses were in the bronchial lymph nodes; general tuberculosis.

4. Thirteen cases in which the bronchial nodes were cheesy; the only other tubercles in the body being discrete miliary bodies in the lungs.

5. Thirteen cases in which all the tubercles of the body were in the bronchial lymph nodes.

The following case was given in illustration: A female, three years of age, sick six days—measles; diphtheria; croup; intubation; pneumonia; death. At the autopsy tubercles of the bronchial lymph nodes were found. A half dozen nodes about the roots of the lungs were enlarged, and exhibited gradations from cheesy masses to discrete tubercles. Bacilli were present in moderate number. The lungs presented the ordinary picture of extensive descending diphtheria and pneumonia. There were no tubercles in them.

This case was regarded as most illustrative. The duration of illness was so brief (six days), and the lesion was sufficiently advanced (certain nodes being quite transformed into cheesy material), to fairly allow the presumption that this well-nourished child was thriving very well until it succumbed to the overwhelming infection of measles and diphtheria.

6. A group of three cases standing out in the one hundred and twenty-five in which the primary infection was obviously in the mesenteric nodes. With this group a few miscellaneous cases were used in unclassified relation.

The cases of Dr. H P. Loomis and Ira Van Giesen were cited in confirmation of the theory. Dr. Northrup then proceeded to inquire if there were any physiological experiments which threw light upon this question, and by way of answer quoted some conclusions of Julius Arnold after dust inhalations in animals, showing how dust (ultramarine) was found in the bronchial lymph nodes (glands) three hours after inhalation; also in what parts of the air passages the dust was mostly found, and how disposed of after suspension of the inhalation for some time. The writer confessed to have found great satisfaction in the explanations afforded by these animal experiments. Dust particles were separately found embedded in the walls of the alveoli, in the lymph canals, and the afferent vessels, forming a continuous chain of evidence as to the course travelled by the particles. No dust was ever found in the vessels leading from the nodes; such filter nodes appearently having the power of collecting and retaining for a very long time the dust particles brought to them.

Experiments by Dobrolousky and Kassokowicz were quoted to show that bacilli can pass the mucous membranes and develop their brood in the lymph nodes without showing any trace of the point of their entrance.

A summary of the 125 cases of general tuberculosis at the New York Foundling Asylum was given as follows: Eighty-eight were of primary bronchial node infection; 3 were of mesentric node infection; 34 were indeterminate. Nine cases were added from Drs. Van Giesen and Loomis.

Dr. Northrup believed that in such cases the inoculation cure of Dr. Koch gave hope of its greatest achievement. This latent tuberculosis he thought might easily account for some of the accidental temperatures experienced in inoculations.

Dr. J. West Roosevelt said that Dr. Northrup's paper was particularly interesting as pointing out the methods of tubercular infection in children. As far as he himself had been able to judge, in adults quite as frequently as in children, the primary infection was in the bronchial lymph nodes. It seemed to him that it was high time that we should give up the idea of infection being caused by direct inhalation of tubercle bacilli. There was no evidence whatever which was capable of explaining the existence of tuberculosis in the lungs except as depending primarily on infection of the bronchial glands or other parts of the lymphatic system. Infection by *indirect* inhalation, as described by Dr. Northrup in his paper, appeared to him to be the most rational explanation of the disease in all cases of pulmonary tuberculosis.

The probable course of events was somewhat as follows: The bacilli, after being inhaled, were arrested by the lymph glands, which became tubercular. After a time cheesy masses from these glands passed through the thoracic duct, either from the right or the left side, and thence into the vena cava. They thus formed a lodgement in the lungs, preferably in the upper lobes, and generally near the pleural surfaces. In a paper which he had read before the Section a month previous, he had endeavored to show how impossible it was to satisfactorily explain the ordinary situation of early tubercular de-

posits in the lungs on the theory of direct inhalation. The lungs were practically a filter, in which we would particularly expect any materials introduced through the venous system to be gathered up. It was thus that they gathered up tubercle bacilli and also masses of pigment. In conclusion. Dr. Roosevelt spoke of gastro intestinal tubercular infection and of the danger that on this account arose from the ingestions of milk and other food containing bacilli.

Dr. William H. Thomson remarked that for a long time past it had seemed to him that on account of the frequency of early tuberculosis in the upper lobes of the lungs there must be some connection between them and the bronchial glands. He had, however, looked upon the matter merely from a theoretical point of view ; but it was now easy to understand the relation which those glands bore to infection of the apex of the lung. Signs of the very early implication of the bronchial glands, he said, were not infrequent in the phthisis of adults. One of his first cases of the kind was in a gentleman above forty years of age, who, with a slight cough and dulness at the right apex, was soon troubled with severe dyspeptic symptoms, and then with intractable vomiting. Great hyperæsthesia of the pharynx then supervened, and soon complete aphonia, which could not be accounted for by the appearance of the vocal cords, which were but slightly congested, and which were never ulcerated. Between the scapulæ, however, the bronchial breath sounds were much exaggerated, and Dr. Thomson pronounced his gastro-laryngeal symptoms as most likely due to enlarged bronchial glands pressing on the pneumogastrics, and that in time he would regain his voice by the softening of these indurated glandular masses. His voice perfectly and rather rapidly recovered twenty-two months afterward, and his gastric troubles simultaneously improved; but soon after this he developed a most agonizing sciatica in both legs, which proved to be due to the formation of a psoas abscess, to which he ultimately succumbed.

Since that time Dr. Thomson had met with several cases of similar vomiting before the formation of vomicæ in the lungs, occasionally accompanied with palpitation of the heart and laryngeal symptoms, both in private and in hospital practice, and he had accordingly insisted in his college lectures that the most effective means for controlling early vomiting in phthisis is repeated dry cupping between the scapulæ.

The Chairman said that as regards one of the points brought forward in Dr. Page's paper, the matter of tuberculous inflammation, it had seemed to him that altogether the simplest way of regarding it was to always think of it as inflammation attended with the presence and growth of tubercular bacilli, whatever other characteristics it might have. The form of the inflammation varied very greatly in different cases, but the tubercle bacillus was always a constant factor. This was seen even in the very smallest foci of tuberculous inflammation, such as the so-called miliary tuberculosis, where with the very simplest elements we always had the tubercle bacillus.

The paper of Dr. Northrnp, he thought, was one of those fortunate productions brought forward at a time when it would be generally regarded as convincing, because the general tendency of thought had been in the direction indicated, and everybody was willing to be convinced. He thought that of late years all our tubercular studies had been tending in this direction. Whether the bacilli were inhaled or swallowed, they were unquestionably liable to make their way, first to the lymphatic glands, and this was therefore the primary infection. Hence Dr. Northrup's argument was all the more convincing because one's mind was already prepared to accept it.

The Price of Quinine has been further reduced, it is said, to twenty-five and thirty cents per ounce.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, December 22, 1890.

Orlando B. Douglas, M.D., President, in the Chair.

The President introduced Dr. Walter B. Chase, President of the Medical Society of the County of Kings, who made some remarks expressive of the harmony and good feeling existing between the members of the two largest medical societies in the State.

The Different Physiological and Therapeutical Properties of the Induced Currents of Electricity, with Especial Reference to Bi-polar Faradization.—Dr. A. D. Rockwell read the paper.

Dr. A. H. Goelet said that, not having heard the entire reading of Dr. Rockwell's paper, he might be guilty of some repetitions. He wished, however, to clear up some points obscure in the minds of the profession regarding the value of the faradic current, and how best to use it. The ordinary conception of faradic machines seemed to be that all were alike, and that it was only necessary that they should make a buzzing noise and shake the patient up thoroughly. This shaking up was usually carried to the point of individual tolerance. It was a wonder that a second application was ever allowed. Such a slip-shod method was to be attributed to scepticism as to any real effect to be obtained from its use. It was also due partly to the fact that we had come to accept a machine constructed by a mechanic without regard to its effects.

Tripier had insisted that there should be two coils, the one of fine wire and long, used for intensity; the other, of coarse wire and short, for quantity. The current from the long fine wire produced sedation by nerve stimulation, and that from the short coarse wire stimulated muscular contraction. They both caused muscular contraction, but the effect in another direction was different. A great deal depended not only upon the length of the coil and the size of the wire, but also upon the rapidity or slowness of the interruptions. To obtain the most sedative effect the interruptions must reach the maximum of rapidity. When it was desired to produce a marked stimulation or contraction of a muscle, a slow vibrator was used.

The current from the long fine wire possessed great stimulating power by reason of its intensity, and when rapidly interrupted it had a decidedly soothing and quieting effect. This was because it produced a tetanoid contraction of the muscles and paralysis of the sensory nerves. The muscles being unable to respond to the rapid interruptions, the contraction became constant or tetanoid. It also produced a marked effect upon the capillary circulation, stimulating contraction and relieving blood stasis. Its effect was always soothing when it was properly applied, even in acute congestions and inflammations.

It was very important that the electro-motor force of the cell, or the current which circulated in the primary coil, should be in such proportion to the vibrator as to make the interruptions smooth and even. For a pronounced sedative effect the secondary coil must be constructed of the finest wire made (No. 40), and its length must be at least 1,700 or 1,800 yards. This coil must be so arranged as to slide easily over the primary ; when the current was started it should be removed from the primary, so that nothing should be felt at first. The increase must be very gradual. But the best effect of the secondary current was obtained only when the secondary coil completely covered the primary, for not until then did the whole coil receive the full amount of induction. This point could not be gained without too great shock with the ordinary battery. He had overcome this difficulty, with the assistance of Dr. Waite, by arranging a rheostat in the primary circuit, so that one or more cells might be tempered to any degree desired. Besides this

advantage, there was another of equal importance obtained by the use of the rheostat at this point. By means of the regulating power afforded by the rheostat, the current could be so controlled that the secondary coil could be slid up over the primary as soon as the vibrator was started, which should be done with the least possible current at first. Then the current could be increased by lessening the resistance in the rheostat. All the while the whole of the secondary coil was receiving the full induction. In other words, both primary and secondary currents were controlled by the rheostat in the primary circuit.

When sedation was desired, the applications must be of long duration, and must start with no sensation to the patient, and never with a jerk. The increase must be so gradual as to be scarcely perceptible, and never to a point to cause discomfort.

He had laid stress upon the sedative effect of the faradic current because it was the most valuable. He did not think the claim for the bi-polar method of its administration had been in the least exaggerated. Its usefulness was not limited to neuralgic affections. It was also effective in allaying the pain arising from congestion, and in relieving engorgement of the pelvic tissues.

Dr. Vineberg referred to his recent observations of the induction current as employed in Paris. Too much importance could not be given the sedative effect of the long fine wire. This was illustrated in the case of a patient at the Mt. Sinai Hospital. She had oophoritis and pain in the pelvis. He applied the finest wire which they had in the hospital, the ordinary form, three coils. It produced no effect. He had the manufacturer place the same apparatus in his office, but with the coil made according to the Tripier system, a wire 1,200 metres long. One application with this current gave the patient relief from the pain for three days.

Apostoli's Cleanliness.—He had been surprised at the pains taken by Apostoli to procure perfect antisepsis in the treatment of diseases of women, and also at the care and time consumed in making a diagnosis, and in treatment of individual cases. His apparatus was simple. Most of his applications were intra-uterine. A false notion seemed to prevail regarding the great strength of current usually employed by him. As a matter of fact, he seldom used more than 150 to 180 milliampères. He had seen no ill results.

Remarks were then made on the treatment of lupus and tuberculosis with the Koch lymph, by Drs. J. H. Linsley, F. M. Warner, Simon Baruch, A. H. Smith, and H. H. Curtis.

Dr. George T. Jackson was elected delegate to the State Medical Society.

The Milk of the Egyptian Buffalo.—According to the researches of Messrs. Pappel and Richmond, of the Khedival Laboratory, Cairo, the milk of the Egyptian buffalo, or gamoose, *Bos bubalus*, presents several characteristics distinguishing it from that of the cow, which may well be remembered by medical men who have to treat patients, especially infants, in Egypt or in other countries where this animal is common. The amount of fat was found to be a good deal larger than in cow's milk, the percentage in the specimens examined varying from 5.15 to 7.35. The sugar, which appeared to be a hitherto undescribed variety, differing from milk sugar, was also found to be of larger amount than that in cow's milk, the average percentage being 5.41. It is suggested that this sugar should be called *tewfikose*. The fat, too, was found to differ from that of cow's milk, containing minute quantities of sulphur and phosphorus, and yielding four times as much caproic acid as butyric acid, whereas in cow's milk the quantity of caproic acid is only double that of butyric acid. The milk was also found to contain a small quantity of citric acid.—*The Lancet*, August 23, 1890.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

DR. KOCH'S LATEST ANNOUNCEMENT—DISCUSSION AT THE HARVEIAN SOCIETY ON KOCH'S METHOD OF TREATMENT—NEPHROLITHOTOMY FOR TOTAL SUPPRESSION OF URINE—THE REGISTRATION OF TRAINED NURSES.

London, January 17, 1891.

The event of the week has been the announcement by Dr. Koch of the actual nature of the fluid used by him in his inoculations for tuberculosis. I scarcely think that any one here is surprised to find that the remedy is prepared from the tubercle bacilli and contains some of their products. Those who have followed Pasteur's researches on the attenuation of virus were prepared to learn that Koch's researches had proceeded on similar lines. The knowledge of the real nature of the remedy will not, I think, alter very materially the present attitude of British physicians and surgeons toward it. This attitude may be described as being one of expectancy and patient experimental enquiry. The first boom of enthusiasm has largely subsided, and those who are using the remedy are now satisfied to wait and observe its action more fully before expressing themselves too decidedly. Those who from the first discountenanced the new treatment can, of course, now point to the morbid source of the remedy as emphasizing all they have said against its use. By the disclosure now made, however, one vantage ground is taken away from the opponents of the new treatment, who can no longer keep on repeating that Dr. Koch and his disciples are using a secret remedy. There is no use in denying that the continued maintenance by Dr. Koch of absolute silence on this point had begun to awaken unfavorable comments—even among laymen. Thus, in the December number of *The Review of Reviews*, the editor of that popular organ trenchantly states: "All dealers in secret remedies are quacks. But Dr. Koch, as far as the retention of the secret of his remedy goes, is as much a quack as Sequard or Count Mattei." The editor goes on to suggest that recent events will probably increase the use of secret remedies by the profession (*e.g.*, Count Mattei's) with a view of ascertaining their real value.

At last week's meeting of the Harveian Society a discussion took place on the subject of Dr. Koch's treatment. Dr. J. Edward Squire read a paper reviewing the present state of our knowledge of the method and giving the results of his own use of it. Dr. Squire thought that the success of Koch's researches in the laboratory justified the use of the fluid in cases of human tuberculosis. Instead of beginning with the largest dose that could safely be borne, equally good results might probably be obtained by using a minimum dose at first and increasing it gradually. In two of his lung cases the large dose of one centigramme was first used; in these a severe reaction occurred. After repeated smaller doses the patients now bore the large dose without any trouble. The same results were obtained by gradually increasing the dose. In most cases the "reaction" was marked by a rise of temperature, but in a few cases the temperature fell to below normal for a time. The pulse became full and soft, and arterial tension was diminished. Various rashes and slight jaundice had been observed, and in one of his cases double vision occurred. As bearing out the theory that only tubercular material was attacked by the remedy, Dr. Squire mentioned two cases where the inflamed area produced by blisters showed no change after injection, while a patch of lupus close by became red and swollen. Fresh air, good food, and cod-liver oil were important aids to the treatment which should not be neglected.

In the ensuing discussion Mr. Noble Smith said he

thought he had witnessed a marked improvement after injections in cases of tubercular disease of the hip and elbow. Dr. Waterhouse related the case of a lady with advanced phthisis whose life had, he thought, been undoubtedly prolonged by Koch's treatment. The temperature decreased, there were no night sweats or diarrhœa, and the bacilli disappeared from the sputa, though much lung tissue was still coughed up; a herpetic eruption appeared on one trochanter.

Mr. Edmund Owen said his mind was still open—wide open—on the subject of Koch's remedy. He thought that the children with tubercular joints who had been injected at the Children's Hospital had not improved more than might have reasonably been anticipated from treatment in hospital upon the old lines—that was, with rest in bed and fixation of the limb. There was one child with tubercular ophthalmia, tubercular dermatitis of the lip, and tubercular disease of the knee. The eye got worse under the injections, the lip got better, and the knee swelled a little, but subsequently appeared unaltered. One patient had been shown as a case of "Koch eruption," and as such was regarded with considerable interest; in due course several other children in the ward broke out in unmistakable measles, thus revealing clearly the nature of the eruption in the first case. Mr. Mortimer thought that if the treatment was to be of service, acute and not chronic cases should be selected.

At the meeting of the Medical and Chirurgical Society, on January 13th, Mr. Clement Lucas read a paper on a case of nephrolithotomy (following nephrectomy performed on the opposite kidney) for total suppression of urine which had lasted five days. Complete recovery had ensued, but, although the operation had been performed five years ago, Mr. Lucas had delayed publishing details of the case, because those to whom he mentioned it, while applauding the attempt to save a life on the extreme verge of dissolution, threw the coldest doubt upon the patient's future. They maintained that even if she recovered from the immediate effects, her life must be a short and painful one—that the one remaining kidney, having been opened and drained, would rapidly degenerate, or another stone would quickly form and bring about a fatal termination of the case. The patient, however, was still living, and in the best of health (she was shown at the meeting), and enjoyed freedom from pain, discomfort, and hæmaturia; these had been almost constantly present for seventeen years before the right kidney had been removed. The operation for total suppression of urine was one that the author had long considered justifiable, and he had on more than one occasion publicly advocated its performance. The operation of nephrolithotomy was performed on the fifth day of anuria, when the patient had become drowsy, weak, and indifferent to what was going on around her. Her temperature was 99° F. A conical stone, rather more than three-fourths of an inch in length and from three-eighths to five-eighths of an inch in diameter, was discovered acting as a ball-valve to the top of the ureter. Urine began to drop out of the wound as soon as the pelvis of the kidney was opened. For twelve days all urine was passed by the wound in the loin. Then an ounce and a half was passed with great pain from the bladder; the quantity gradually increased, and after the nineteenth day all the urine was passed naturally. The wound remained aseptic, and healing was complete in ten weeks.

For some time past the desirability of having some system of registration for trained nurses has been discussed. What promises to be the thin edge of the wedge has just been introduced by the publication (by the British Nurses' Association) of the First Annual Register of Trained Nurses. Of course this register has no legal authority, and can in no way be compared with the Medical Register. It may, notwithstanding, prove to be the precursor of some authorized system of registration, and thus put a check on the recognition of incompetent and inadequately trained nurses.

SOME REMARKS ON THE EARLY TREATMENT OF OTITIS.

To the Editor of the Medical Record.

Sir: The medical man who sees a case of otitis media which has suddenly developed during the progress of catarrhal inflammation of the air tract of the head, whether consequent on scarlet fever, cold in the head, or other affection, assumes a serious responsibility unless well informed in its management, since under certain conditions a seemingly mild case may speedily become most painful and grave. I have recently been reminded of the perplexity, not to say apprehension, felt by the conscientious practitioner when untoward symptoms develop, several distressing cases coming under my observation in consultation with other physicians. The urgency of the cases seen was no doubt due to the severe winter weather of late prevailing. I hope I may be permitted to offer some practical suggestions drawn from such experience, since they may be of interest to others when in doubt as to the best course to pursue.

It would be out of place here to go far into the pathogenesis of otitis, but we may assume that acute middle-ear affections are, generally speaking, divisible into two principal groups; namely mild and severe. The mild ones are usually preceded by more or less earache, which almost wholly disappears on the occurrence of a discharge from the ear. The pain is due to inflammation of the mucous-periosteal lining of the drum (inflammation limited, indeed, for the most part to the atrium of the drum) and the confinement of secretions, which may be either moderate or profuse in quantity. Beyond cleansing the organ by means of cotton-wool pellets and very gentle syringing while discharge lasts, these cases had best be let alone for the most part, inasmuch as they have a tendency to spontaneous recovery. Though these cases often get well despite misguided treatment one should never be lulled into unguarded security, whereby valuable time may be frittered away in useless treatment when severer symptoms may be impending. In a severe case it would seem almost impossible to be mistaken in diagnosis if the ear were properly examined even before the more urgent symptoms fully develop. The pains and headache are soon unremitting, unendurable, more agonizing, perhaps, than the pains of almost any other disease, and they demand instant relief, if attainable.

Much blame, we fear, for children's dreadful sufferings specially, not to mention the imminent danger to life, frequently lies at the door of writers who fail to differentiate between mild and severe cases, and who too often recommend for both of them such treatment as may, for the most part, be found among the rubbish of ancient writings called medical; methods meddlesome and often brutal when zealously employed; liable, indeed, to be followed by sad results, now and in the future. Waste no time, therefore, in temporizing measures, since the relief to be had should be quickly sought. So soon as the pains are great, no relief following the discharge, if any occurs, and the upper edge of the drum-head becomes red and bulging, it may be suspected that the gravity of the symptoms is mostly due to the confinement of secretions in the bony chamber comprising the loft above the main cavity of the drum—the attic of the drum in fact—a space lying almost entirely above that part of the drum which is seen on looking into the ear to be covered by the drumhead. The swelling of the lining membrane of this unyielding bony cavity closes the natural outlet for secretions, which can now only escape from the attic by dissecting their way slowly underneath the membrana flaccida and finally appearing as a tumefaction there or further along the bony portion of the external auditory canal. Finally, the mastoid process or general outer surface of the temporal bone may be invaded with formation of abscess of varying proportions.

The onset of this unfavorable process must be recognized at once if we would prevent extensive trouble;

puncturing the drumhead low down, blistering, leeching, poulticing, etc., will do no good; indeed, quite the contrary, since they may distress the patient and increase the local irritation. As the invasion of the trouble is rapid, so the remedy should be sure and swift; no stabbing the drumhead in the dark or fruitless incisions into the canal. Let a careful examination of the parts (patient narcotized if unable to remain quiet—which in children cannot be expected) with the electric lantern worn upon the forehead be made. Fortunately we may now, if timely, relieve the symptoms at the start, by thus liberating the fluids in the attic and establishing drainage, an operation based upon the principle inaugurated in the treatment of these parts by Wilde, who waited, however, until much damage had been done before seeking to give relief by letting out matter presenting at the mastoid process.

Do not, therefore, wait for days while more and more damage is being done, when the extension of inflammation from the seat of disease may be prevented by a fine incision through the membrana flaccida, a proceeding speedily followed by relief in most cases, and in many by a speedy cure. To make the incision a small, sharp-pointed bistoury, the shank of which is set at a convenient angle to its handle, should be employed. The point of the instrument is then to be advanced through the membrana flaccida well up into the attic, and as it is withdrawn a free incision made through any bulging or swollen tissues of the canal in proximity to the membrane.

Any one who has witnessed the immediate relief following the liberation of confined secretions, specially from underneath deep fascia or the periosteum can appreciate the importance of this operation. Of the subsequent treatment but little need be said; it will depend largely upon the injury already inflicted upon the ear; if done early, usually no further special treatment will be required.

Hoping the above may draw the attention of the practitioner to this important procedure when treating these cases, I am Yours,

SAMUEL SEXTON, M.D.

12 WEST THIRTY-FIFTH STREET, NEW YORK.

New Instruments.

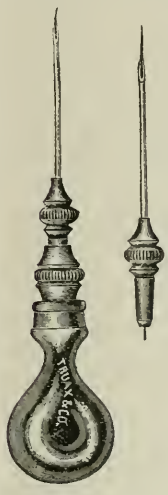
AN IMPROVED INSTRUMENT FOR ADMINISTERING HYPODERMIC INJECTIONS.

BY JOHN J. THOMAS, M.D.,

YOUNGSTOWN, O.

THE subcutaneous method of administration of remedial agents is one that was never so widely or so generally resorted to as at the present time. The last decade has witnessed a decided enlargement of its applications. The syringe is resorted to much more frequently than formerly, and the drug manufacturers vie with one another in the completeness of their stock of remedies specially prepared for hypodermic use. The instrument manufacturers, also, exhibit a variety of syringes, each one guaranteed the most reliable and the least liable to be found out of order when its use is called for, but each one constructed upon the same general principle, equally complicated, and very nearly equally unreliable. What practitioner of medicine has not, time and again, found his hypodermic syringe out of order, the glass barrel broken, or the plunger dry, and the whole apparatus unfit for immediate use, and at a time when its use was most urgently demanded. Is it too much to say that untold and prolonged suffering can be laid to the imperfection of the ordinary hypodermic syringe? It is not too much to declare that lives have been lost from the inability on the part of the physician promptly to deliver an injection of ammonia, whiskey, nitro-glycerine, or ergot. The fault is with the principle of the construction of the ordinary syringe. The cylinder and piston principle should be laid aside and substituted by something simpler and less complicated.

Nearly two years ago I made an apparatus for giving hypodermic injections by tying the open end of an ordinary medicine-dropper bulb over the screw end of a hypodermic needle, using care to make the connection perfectly air-tight. Flattening the bulb and inserting the needle into some water, I found that the former filled with the fluid in about twenty-five or thirty seconds, varying with the strength and firmness of the bulb and the calibre of the needle. The capacity of the average bulb was found to be twenty-eight or thirty minims, about the same as that of the barrel of an ordinary syringe. Redischarging by pressure, making the solution from the tablet and refilling the bulb took but a little time, and I soon began this simple means of delivering injections, and found the method to be as satisfactory as could be desired. The first filling of the bulb was merely to measure its capacity and to insure that the second filling be perfect and without the admixture of air. Firm and equable pressure by the thumb and fingers upon the bulb would insure the delivery of every drop of the solution, the needle being withdrawn before allowing the bulb to expand. At first I was accustomed to keeping the needle and bulb separate, attaching them before the occasion requiring their use. This was found unnecessary, as the bulb and needle could be easily dried by collapsing and expanding the former a few times over a lamp or near the fire. It was found that this little instrument was always in good order and could easily be kept clean. I discovered no appreciable tardiness in effect when so large an amount of solution as twenty-eight minims was injected. I made five or six of these syringes at practically no expense save the slight cost of the bulbs, utilizing some old needles. I placed one or two in my buggy-case and surgical and obstetrical bags, and found myself in the ready possession of a reliable means of giving an injection upon any and every occasion. For upward of two years I have used none but the little instrument in question, and with ever increasing satisfaction.



In the *Medical and Surgical Reporter* of September 28, 1889, I described the contrivance, inviting the instrument makers to adopt the principle in the manufacture of a perfected syringe. After using the instrument for a year longer I wrote for the same journal a second article upon the subject, appearing in the issue of October 25th. The second article in particular attracted considerable attention, and a well-known firm of instrument makers of New York City, and another of Chicago were readily induced to manufacture the syringe. The syringe used by Koch in the injection of the lymph for the cure of tuberculosis appears to be constructed upon the same general principle.

Having recently seen a woodcut of the latter, I should judge it to be unnecessarily complicated for all ordinary purposes. The great merit of the bulb syringe made by Messrs. Charles Truax & Co., of Chicago—a woodcut of which accompanies this article—lies in the extreme simplicity of its construction. The bulbs are of two sizes, the larger being intended chiefly for the injection of medicaments necessarily bulky, such as the diffusible stimulants, and the smaller for solutions of the alkaloids.

Men of the highest standing in the profession assure me that the bulb syringe will eventually supersede the instrument now in common use, if only for the fact that the use of the former affords a means of delivering an injection in a perfectly *aseptic manner*. The chance of the

occurrence of abscess is minimized, the bulbs can so easily be made and kept surgically clean. Aside from its claims to being fully in line with the demands of the times in the direction of asepticism, the bulb syringe embodies a great improvement in the direction of simplicity, durability, and efficiency.

QUILL DRAINAGE-TUBES.[1]

By OTIS K. NEWELL, M.D.,

SURGEON TO OUT-PATIENT DEPARTMENT, MASSACHUSETTS GENERAL HOSPITAL, BOSTON.

Dr. Beach has used for the past two years, at his clinic, drainage-tubes made from large-sized imported goose-

quills, such as are used for making the finer grades of camel's-hair brushes. The quills are taken without cutting off the dermal end, and perforated at intervals with an ordinary round leather punch. As shown in the figure, a delicate and smooth probe-pointed tube is thus provided, presenting the maximum lumen and minimum thickness of wall. This tube is made from a natural dermal appendage and is absolutely unirritating. It can be readily cut with scissors, and is not fragile like glass. It does not form any of the irritating chemical changes such as are frequently seen where rubber tubes have remained for any length of time. These tubes are preserved in corrosive sublimate or carbolic-acid solutions, and are easily sterilized.

[1] Reported from the clinic of Dr. H. H. A. Beach, at the Massachusetts General Hospital, Boston.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 25, 1891, to January 31, 1891.

Patzki, Julius H., Major and Surgeon. By direction of the Secretary of War, granted leave of absence for six months, with permission to go beyond sea. S. O. 24, par. 5, A. G. O. Washington, D. C., January 29, 1891.

Stephenson, William, Captain and Assistant Surgeon. By direction of the Secretary of War, will proceed without delay from Columbus Barracks, O., to Fort Wayne, Mich., and report in person to the commanding officer of that post for temporary duty, and upon completion thereof will return to his proper station. S. O. 23, par. 13, A. G. O., Washington, D. C., January 28, 1891.

Gibson, Robert J., Captain and Assistant Surgeon. By direction of the Secretary of War, relieved from further temporary duty in the field, to take effect so soon as his services can be spared by the officer commanding the tooops with which he is serving, and will then return to New Haven, Conn., and resume his leave of absence. S. O. 22, par. 6, A. G. O., Washington, D. C., January 27, 1891.

Gandy, Charles M., Captain and Assistant Surgeon. By direction of the Secretary of War, relieved from temporary duty in the field, to take effect when his services can be spared by the commanding officer of the troops with which he is serving, and will then return to Ocean View, Cape May County, N. J., and resume his leave of absence. S. O. 21, par. 1, A. G. O., Washington, D. C., January 26, 1891.

Owen, William O., Jr., Captain and Assistant Surgeon. By direction of the Secretary of War, relieved from temporary duty with troops in the field to take effect as soon as his services can be spared, and will then return to Muskogee, Indian Ter., and resume his leave of absence. S. O. 20, par. 3, A. G. O., Washington, D. C., January 24, 1891.

Cowdrey, Stevens G., Major and Surgeon. By direction of the Secretary of War, the extension of the leave of absence granted in Special Orders No. 302, December 27, 1890, from this office is still further extended two months on surgeon's certificate of disability. S. O. 19, par. 13, A. G. O., Washington, D. C., January 23, 1891.

Reed, Walter, Captain and Assistant Surgeon. By direction of the Secretary of War, relieved from temporary duty at Fort Keogh, Mont., to take effect as soon as his services can be spared by the commanding officer of that post, and will then return to Baltimore, Md., and resume his duties in that city as Attending Surgeon and Examiner of recruits. S. O. 20, par. 3, A. G. O., Washington, D. C., January 24, 1891.

Gardner, William H., Major and Surgeon. By direction of the Secretary of War, relieved from further duty in the field, and will return to his proper station. S. O. 19, par. 2, A. G. O., Washington, D. C., January 23, 1891.

Official List of Changes in the Medical Corps of the United States Navy for the week ending January 31, 1891.

Crandall, R. P., Assistant Surgeon. Ordered to examination preliminary to promotion.

Berryhill, T. A., Passed Assistant Surgeon. Detached from the McArthur, and wait orders to the Marion.

Jones, W. H., Surgeon. Detached from the Swatara, proceed home, and granted six weeks' leave.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 31, 1891.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	13	3
Scarlet fever	174	23
Cerebro-spinal meningitis	3	3
Measles	433	32
Diphtheria	107	28
Small-pox	0	0
Varicella	29	0
Pertussis	0	11
Croup	0	0

Micro-Organisms in Great Cities.—Professor Tarnier in his course of lectures on obstetrics, in 1890, referred to M. Miquel's researches on the relative abundance of micro-organisms in different places (*The British Medical Journal*). One to the cubic metre of air is the proportion at the top of a high mountain. In the Parc de Montsouris, in the south of Paris, M. Miquel found 400 micro-organisms to the cubic metre of air, while in the Rue de Rivoli the proportion was 3,480. In a new room in the Rue Censier he found 4,500 to the cubic metre; more, that is to say, than in the centre of Paris in the open air. In a room in the Rue Monge, he counted 36,000, in the Hôtel Dieu 40,000, and in the Pitié, an older hospital, 319,000 micro-organisms to the cubic metre. At the Observatory, Montsouris, 650,000 microbes were found in a gramme (15 grains) of dust; in the room in the Rue

Monge the amount was 2,100,000. In the hospitals the proportion was so high that counting the number of microbes in a whole gramme of dust was found to be impossible. The dust is the great conveyer of micro-organisms. At 2 A.M., when a city is most quiet, the fewest germs are to be found in the air, at 8 A.M. the industry of domestic servants and dustmen has already made the air teem with germs. At 2 P.M. the proportion has again greatly fallen; at 7 P.M. it is once more high, for many houses are being "tidied up;" besides sundry kitchen operations are unhygienic. Thus the "small hours," unfavorable in many respects to patients hovering between life and death, are the least septic of the twenty-four. The day proportions indicate that household duties cause more septic diffusion than is excited by traffic and industry.

Doctors and Advertising.—Bitter complaint, says the *London Daily News*, is heard from the medical profession regarding the severity of the unwritten law of professional etiquette. It is not that medical men are forbidden to advertise themselves; it is that they are constantly under suspicion of advertising themselves when they are really doing nothing of the sort. Lecturing is just now the bone of contention. If a medical man has the gift of public speaking "on every conceivable topic," as somebody has sneeringly put it, why cannot he be allowed to instruct and entertain his fellow-creatures from a public platform? And if the committee of the local literary and scientific institute will print the name of "Dr. Abernethy Astley Cooper Jones" in big type, with a whole row of initials after it, is it fair to make him responsible for that? A medical correspondent of *The Lancet*, who from obvious motives suppresses his name, confesses to finding "intense pleasure and relaxation in addressing an intelligent audience," but he had to endure "the darts of slander." A friend of his, a medical man of similar ability and most excellent literary attainments, loved and respected by all who come in contact with him, has the fortune, or misfortune, to be one of our best public speakers. He can make ten guineas by one evening address, and earn as much in an hour and a half as his detractors can do in a week, but, owing to the "intolerable priggish attitude" of his fellow-practitioners, he is obliged even to cease his gratuitous efforts on behalf of the churches, chapels, and local charities.

All about Bacteria.—Just now, when so much interest has been aroused anew in the subjects connected with bacteriology, and a widespread desire is evinced among medical men to know more about micro-organisms, in all their relations, one is greatly impressed by the scarcity of good books on this subject in English. Notwithstanding the vast amount of literature treating of almost every other medical subject, from the most varied stand-points, yet there is on bacteriology alone, now, not a single text-book published in this country that represents, in at all satisfactory way, the present aspects of our knowledge.

There are numerous works in German, French, Italian, etc., and one or two translations from the German have been published in England, but none in America. As so many, not familiar with the subject, are looking for such a book, a word or two about one of the newer works may not be amiss.

One of the best and most readable books in German, is Fraenkel's "Grundriss der Bacterienkunde," the third edition of which was published last year. It is arranged in the form of a course of lectures as delivered in the University of Berlin, and has the great advantage over many other works that it treats in not too great detail, bacteriological technology, including morphology and biology of bacteria, methods of investigation, staining, culture, etc., and also the most important pathogenic and non-pathogenic micro-organisms, the present state of our knowledge including methods of culture, differentiations, stains, etc. The book commends itself not only because of the high standing of the author as a bacteriologist, but also because of his clear, satisfactory, and not too technical manner of treatment of his subject. We are informed that a translation of this book, by a competent bacteriologist, is soon to be published in this city, and we would warmly commend it as one that will furnish such information as both the practitioner and the practical worker in bacteriology desire.

Is Removal of the Tonsils Dangerous?—Removal of the tonsils by the bistoury or guillotine is a popular operation in this country. The French are less partial to it, and MM. Quenu and Lucas Championnière have recently dwelt on its dangers at the Paris Société de Chirurgie. The latter surgeon referred to two cases in Broca's practice where profuse hemorrhage followed removal of the tonsils. In one of these instances the patient, a medical student, died almost immediately after one tonsil was cut, so violent and uncontrollable was the bleeding. In a case in M. Lucas-Championnière's own experience, the patient, a middle-aged man, had enlarged tonsils, quite free from inflammation, and he was not subject to any morbid condition liable to prevent the natural arrest of hemorrhage. On removal of one tonsil hemorrhage took place, and could not be checked until after two hours of digital pressure with a tampon soaked in ergotin. M. Quenu always uses the galvano-cautery three or four times, at intervals of a fortnight, and atrophy of the tonsil always follows. MM. Marc Sée and Chauvel do not dread the knife. There can be no doubt that hypertrophy of the tonsils requires active treatment, especially in youth; the evil consequences of neglect are well known. In the majority of cases the risk of dangerous hemorrhage is very slight; but the possibility of its occurrence should always be borne in mind, and the use of ice or of a styptic gargle should be enforced as a measure of precaution immediately after the operation. —*British Medical Journal.*

"Where Much is Given, Much is Required."—Dr. Andrew H. Smith writes: "May it not be that success in the Koch treatment depends upon a certain relation between the amount of the dose and the amount of tuberculous tissue present in the system? In lupus, for example, the lesion being only skin-deep, and the affected surface usually not large, the quantity of tuberculous tissue is insignificant when compared to the masses of such tissue found in advanced pulmonary tuberculosis. Hence a milligramme of the fluid, for example, expending its whole energy upon this small quantity, produces a decided impression upon it, and after a few repetitions, effects its entire removal. The same quantity of fluid, on the other hand, would have no sensible effect upon the massive deposit of confirmed phthisis, and if the dose were increased in proportion to the work to be done, the reaction would be fatal to the patient. A small amount of coal requires but a small amount of oxygen for its consumption, and produces but a small fire. A large amount of coal requires a large amount of oxygen, and makes a large fire. Unfortunately, we cannot take portions of the pulmonary tuberculous tissue and act upon them in detail. The coal must all be ignited at once, and with oxygen enough to insure combustion the result would assume the proportions of a conflagration. Herein, I think, will be found the necessary limitation of the usefulness of the Koch treatment in pulmonary disease. If we can get our cases when the amount of tissue is not more than in lupus or in joint tuberculosis, we shall probably have as good results as are obtained in these affections. But when the tuberculous tissue is to be measured by cubic inches, or tens of cubic inches, no quantity of lymph which the system will bear will produce any sensible effect upon it."

When the Stomach rebels against cod-liver oil it is recommended by some practitioners to make use of inunctions instead. The chest and abdomen are the sites usually chosen, and notwithstanding the objections to the "greasiness" of the method the results are quite satisfactory.

PERINEORRHAPHY: A PLEA FOR IMMEDIATE REPAIR.

WITH THE DESCRIPTION OF A NEW METHOD OF SUTURING.

BY CLEMENT CLEVELAND, M.D.,

SURGEON TO THE WOMAN'S HOSPITAL IN THE STATE OF NEW YORK.

IT is not from a want of literature on this subject that I am led to make choice of it for a paper to be read before the Practitioners' Society, but because of a belief that appears to exist in the minds of many practitioners, to the effect that rupture of the perineum is of little importance, unless it has extended through the sphincter ani.

An experience, which has extended over many years, in observing the results of the lesion at the Woman's Hospital, has led me to form very positive convictions in favor of immediate repair of the injury; and the hope that I may be able to convince others of the soundness of this view has been the inspiration of this paper.

A thorough knowledge of the anatomy and physiology of the structures which form the floor of the pelvis is necessary to enable us to understand the full importance of this lesion. At the risk, therefore, of being a little tedious, I will briefly review the more important points, that I may be the better able to defend the position in which I find myself, that of maintaining that no primary rupture into the body of the perineum is insignificant or unimportant. I wish to be understood in this statement to refer only to the primary tear. The consideration of the lesion after cicatrization has taken place is another matter, and depends upon an entirely different set of circumstances and pathological conditions.

By floor of the pelvis is meant that portion of the body lying between the pubic bones and the sacro-sciatic ligaments and coccyx, and is composed mainly of muscles, connective tissue, and fasciæ. The muscles are the superficial and the deep. The superficial are the bulbocavernosus, erector clitoridis, transversus perinei, sphincter ani, levator ani, and coccygeus. The deep are the deep transversus perinei, constrictor vaginæ, and depressor urethræ.

The fasciæ are the superficial and deep perineal. The levatores ani, transversi perinei, and perineal fasciæ are the structures chiefly concerned in the support of the pelvic viscera, and whose functions are disturbed by the rupture of the perineum.

In pregnancy the vagina is enlarged by a process similar to that going on in the uterus, a physiological hypertrophy of all its tissues. There is a marked increase in its circulation and that of all underlying structures. The muscles and fasciæ of the pelvis are softened by the increased supply of blood and serum. The development of the organ keeps pace with the enlargement of the uterus. At the time of labor it has become softened and distensible. Its muscular contractility, also, seems to have increased. After labor the retrograde metamorphosis, or involution, reduces the vagina to its normal dimensions. This process is supposed to be a fatty degeneration of the hypertrophied tissue. The operation is sometimes arrested in its progress, leaving the vagina in a state of so-called subinvolution. It does not come within the scope of this paper to discuss at length the etiology of this condition of subinvolution. It is sufficient for our purpose to describe the lacerations of the perineum and associated muscles and fasciæ, as they form the most important factors in its causation and furnish the indications for the operative procedure.

For convenience the various injuries may be divided as follows. The list does not include tears of the fourchette, which are merely ruptures of the mucous membrane and a natural result of labor, and may be dismissed as unimportant:

1. Lacerations into the body of the perineum, including all, from those slight in amount to those extending to the sphincter ani, without appreciable injury to the levators. 2. Rupture of the perineum with radiating tears into the sulci. 3. Rupture of the perineum through the sphincter ani without injury to the levators. 4. Rupture through the sphincter with lacerations of the levators. 5. Includes those cases where there is greater or less relaxation of perineum and vagina from subinvolution, due to overstretching and hidden minute tears in the muscular fibres, with no visible laceration of perineum or vagina. A very large number of cases are embraced in this class, and most of them would be overlooked if the observer trusted to external appearances alone, and did not test the strength of the perineum by digital touch. Gentle stretching will afford abundant evidence that the strength and retractile power is greatly diminished.

A pathological result that is likely to follow any or all of these injuries is a condition that has been denominated subinvolution, which has for its direct cause the congestion consequent upon the injuries, and possibly, to some degree, the hyperæmia set up for their repair.

Relaxation is the ultimate result, supposedly from malnutrition in the muscular structures in a condition of subinvolution. Then may follow retrocele, cystocele, the various displacements, prolapsus.

I have thus briefly run over the main facts and results, in their pathological order, of injuries to the perineum and pelvic floor that lead me to hold that no appreciable rupture is unimportant at the time of labor.

The logical sequence of this position, then, is, that for the sake of prophylaxis immediate repair should be advocated as a rule. This brings us to the consideration of the subject of repair, as it relates to the primary and secondary operations, and the methods to be employed. First and most important is the treatment of the condition immediately after labor. Is the lesion to be repaired at once, or left till cicatrization has taken place, or later? There are cases where operation must be postponed, but they form the exceptions. The consensus of opinion among gynecologists is in favor of immediate operation as a rule of practice. There is every argument in favor of it, and not a valid one against it. By *immediate* is meant any time within one or two days, though the preferable time is within the first hours after labor. Then it is a simple and easy operation to perform. An anæsthetic is rarely necessary. The application of a little ten per cent. solution of cocaine will effectually deaden all sensibility for the short time required in passing the sutures. It may be necessary to cut off one or two ragged points, and at most only a few stitches will be required. When well done it rarely fails. It is easier to bring the torn structures into normal coaptation, and they are also more securely shut off from septic discharges thereby. If successful, it prevents or lessens the probability of subinvolution, and renders unnecessary a severer operation at a later date. The repair of the

lesion, when it has extended through the sphincter, is a little more difficult task, but only slightly so, and usually the healing is most kindly.

I will venture to say that fully two-thirds of the operations we are performing for the cure of this lesion at the Woman's Hospital would not be required if the injuries had been repaired at the time of confinement. If this is true with us, what must be the multiplied result throughout the city?

Now as to the methods to be employed.

The one to be selected should be scientific, and, to be so, must be based upon correct pathological conditions. There have been many ingenious devices, originated by clever and eminent men, for the repair of the various lesions of the perineum and pelvic floor, and their discussion is full of interest to the special student, but they do not come within my present design, which is to treat of methods that are capable of wide application, methods that are simple in detail and rapid in execution, and suitable also for the immediate and the secondary operation.

To my mind the one that fulfils most of the requirements, is thoroughly scientific, and nearest to universal application, and, moreover, has stood the test of time, growing more and more popular the better it is known and understood, is the one devised by Dr. Emmet. It is based upon the indisputable pathological fact, that most tears extending inside the perineum do so in the line of least resistance, and that is into the sulci that lie to either side of the vagina. The method aims to make a denudation as near like the original tear as possible, and to correctly restore the separated structures to their normal attachments.

This method, however, is hardly the one to employ in the immediate operation, unless the operator has made himself the master of all its details. It is simple enough when thoroughly understood, and will amply repay anyone for making himself familiar with it. In the hands of the inexpert, the large number of stitches, if of silver wire, which Dr. Emmet uses exclusively, passing in three different directions, may produce sloughing in the centre and leave an open wound to heal by granulation. I do not mean the whole wound, but the centre portion, below the crown stitch, where the sutures come together. It is true, as Dr. Emmet claims, that this rarely affects the ultimate success of the operation, as the closure of the angles is the main point to be attained, and they always hold. Sloughing is not, however, a comfortable thing to have occur, and may be a dangerous thing. If catgut is employed this accident is not as likely to happen, as it, the catgut, readily softens and yields to the tumefaction of reparative hyperæmia.

It would seem desirable, therefore, to find some method of passing sutures that is not complex in any of its details, and which affords an easy way of closing the primary rupture, and practically accomplishes the result aimed at in the Emmet operation. This, I think, is attained by the method I will now describe with the aid of a diagram. The sutures are introduced exactly in the same way, whether the operation be primary or secondary. I have chosen to represent them here as applied in the secondary operation, as that suits my purpose a little better, and answers perfectly well the purposes of illustration.

The usual broad denudation, extending well into the sulci, having been made, the first suture is passed in at the centre (1, Fig. 1) of the denuded surface on the patient's left, a quarter of an inch from the edge, is carried well back, deep under the tissues, to embrace the retracted muscles, across between the denuded surface and the rectum, to the centre of the denuded surface, then down and out a quarter of an inch from the edge, at a point (2, Fig. 1) midway between the centre of the denuded surface on the patient's right, and the posterior commissure, *D*. It is then carried over without cutting, and entered at a corresponding point (3, Fig. 1) on the patient's left, directly opposite the point where it was brought out; then carried up, buried, to the centre of the denuded surface, across, and out a quarter of an inch beyond the centre of denuded edge (4 *A*, Fig. 1), directly opposite the point where it was first introduced. This suture is marked *A* on the diagram.

The second suture, or suture *B* in diagram, is introduced just below the summit of the denudation on left labium ((1) *B*, Fig. 1), and passed, buried, close to the denuded edge, around the angle in the left sulcus to the highest point of denuded surface on the columna, at *C*, Fig. 1, then across, still buried, the angle of right sulcus and out at (2) *B*, Fig. 1, which is a point midway between summit and centre of denudation on right labium; then carried over without cutting, and is entered at (3) *B*, Fig. 1, a point corresponding to the one

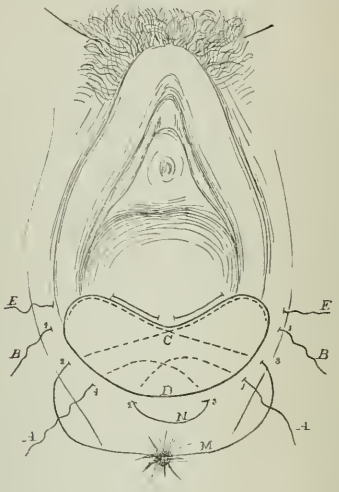

FIG. 1.

where it was just brought out, then across, buried, the angle of left sulcus to the point *C*, and finally passed around the angle of left sulcus close to the denuded edge and out at (4, *B*, Fig. 1) a point corresponding to (1) *B*, Fig. 1, where it was first introduced.

As an extra precaution, and to prevent dragging, when catgut is used for the other stitches, *A* and *B*, I introduce usually a third, after the manner of Emmet's crown stitch, though not for the same purpose, and call it the protection suture. It is marked *E* in the diagram, and should be either of silver wire or silkworm gut. It is entered close to the summit near point (1) *B*, carried through the labium and out on the mucous membrane, then takes up about a third of an inch of mucous membrane on the columna at *C*, then passes through the summit of right labium.

The sutures are now tied, beginning with the lowest, *A*. By drawing upon the ends of this suture it will be observed that the loop *N* is tightened, and the points (2) and (3), *A*, Fig. 1, are brought together; then, by bringing the ends over and tying, the points (1) and (4), *A*, Fig. 1, are brought together, completing the first suture. We have practically two sutures with but one tying. The second suture, or suture *B*, Fig. 1, is next secured. By drawing on the ends loop *M* is tightened, the points (2) and (3) *B*, are approximated, and the highest denuded point at *C*, on the columna, is brought forward to them; then, by bringing the ends over and tying, the angles are closed separately, and the operation is completed, unless the protection suture has been used. Thus, then, are practically four sutures with but two tyings. When the protection suture is used, it is secured last. It is unnecessary when silkworm gut, or silver wire, is used for suture *B*.

In extreme cases of extension of the laceration into one or both sulci, a combination of the Emmet sutures, to close the upper portions of the angles, may be used with this method, or the same form of suture may be used for the angles also. In diagram, *L* and *R*, Fig. 2, (*L* marks the angle of left sulcus), are represented three sutures introduced after the Emmet method, that, when tied, will draw the angle up toward the ramus of the pubis. At *R* is the angle of right sulcus, with one suture introduced after the manner proposed above. It will be seen that, as the ends of this suture are drawn upon, the loop *O* is tightened and the points (2) and (3) are approximated, and, when the ends are tied the whole angle is drawn up, quite as much as it would be had the sutures been introduced as at *L*.

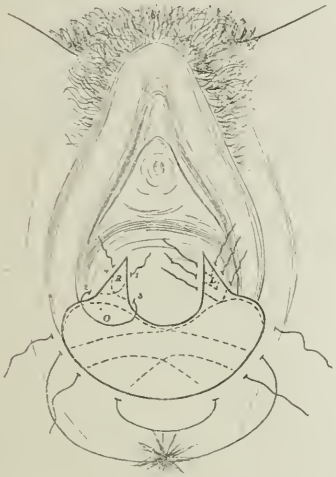

FIG. 2.

The angle sutures should be first introduced, and the operation then proceeded with after the method described.

In lacerations through the sphincter I believe the method, with a slight modification, will prove useful. The sutures for closing the rent in the bowel should be first introduced. Here I prefer the continued suture of catgut. The others are then to be passed after the manner before sketched, with this exception, viz.: to substitute for the lower suture (suture *A* of the diagram) two transverse sutures, the reason for this being that, if my suture were used, at the point where the two portions of the suture would cross each other, which would be directly over the rent in the anus and rectum, there would be a liability to too much dragging. The upper suture (suture *B* of diagram) should be retained. In some cases it may be found advantageous to introduce even another figure-of-eight suture below suture *B*. Thus far I have employed this method in eight cases, all of which were most satisfactorily successful. I mean by this, that not only were the rents closed, but the very thing which is essential in the proper restoration of the perineum, the drawing of the vagina up to the pubic rami, was markedly accomplished.

Catgut and silkworm gut are preferable for the sutures, though any kind of material usually employed may be made use of here.

Farther observation, I believe, will lead me to continue the use of catgut and retain the protection suture, as an essential part of the operation. For the protection suture I have used both silkworm gut and silver wire. One answers the purpose as well as the other.

The time required for the performance of the operation by this method is from ten to fifteen minutes. Time is of importance in any case, and especially so where, as frequently happens, it is necessary to repair both cervix and perineum at the same sitting. All the time that can be saved in etherization, other things being equal, is of advantage to the patient.

In sewing the primary tear I believe there is an especial field for the method. As there is no denudation to make, the whole operation should not occupy more than five minutes. In some cases it will be found necessary to use but one stitch "*B*," Fig. 1. By this method the raw surfaces are securely shut off from infection by septic discharges.

The requirements for the proper restoration of the ruptured perineum are, then: simplicity in technique, ease and rapidity of execution, and thoroughness with which the torn structures can be restored to their normal attachment. These I believe are fulfilled in a large degree by the method I now offer for discussion.

STUDIES IN THERAPEUTICS—ANTIPYRIN.

By JOHN AULDE, M.D.,

PHILADELPHIA, PA.

ANTIPYRIN is a remedy originally introduced to the attention of the medical profession as an antipyretic, hence its name, and although a proprietary article it has been used quite extensively throughout the world. A large mass of material has accumulated in the shape of reports from physicians, and perhaps a majority of the profession have determined in their own minds the special classes of disorders in which it may be used with advantage; others, less observant, doubtless have not formed any very definite ideas in regard to its use, and principally for them, and for the historical value which it will possess, the following observations have been prepared.

Materia Medica.—Antipyrin (dimethyloxychinicine, or phenyldimethylpyrazolon) is a synthetically prepared product in the form of a white, crystalline powder, or scales, obtained from the destructive distillation of coal-tar by a private and complicated process. It is freely soluble in cold water, but less so in alcohol, ether, and chloroform. Dose, 5 to 30 grains, in peppermint water, with a little syrup; it is also used hypodermatically, in the same dose, with warm water, and by the rectum in the case of heat-fever, to reduce temperature. Dose for a child five years of age, not more than 4 grains, to be repeated at intervals of three or four hours.

Pharmacology.—The ingestion of lethal doses of antipyrin is attended with restlessness, great anxiety, slow and labored respiration, with more or less giddiness, symptoms which should be combated by the administration of diffusible stimulants, small doses of nux vomica, together with the inhalation of pure oxygen gas, or the practice of artificial respiration. When it is impossible to adopt these measures immediately, cold applications are to be made to the entire body, as it has been demonstrated that cold postpones the toxic effects of the drug. Synergists include all remedies which have a depressing action upon the organism, except cold.

The experiments of Batten and Bokenham [1] indicate that antipyrin in lethal doses affects both the brain and spinal cord; the most pronounced symptom, that is, the condition most uniformly noted, being rigidity of certain sets of muscles. In frogs this occurred first in the forelegs, and in the hinder extremities of guinea-pigs. Rhythmical movements of the limbs followed, as if the animal was attempting to walk, although it remained lying on the side. At times the use of the forelegs was regained, when circular movements, always in the same direction, followed, the hind legs being used as the pivotal point. Later, extreme irritability came on, when a draught of air, a footfall, a vibration, or a slight tap was sufficient to produce convulsive movements, effects due apparently to the

[1] British Medical Journal, June 1, 1889.

influence of the drug upon the nervous system. They concluded, finally, that these convulsions were of spinal origin rather than cerebral. A strange coincidence should be mentioned in this connection, viz.: When toxic doses are administered to animals under anæsthesia, convulsive movements are postponed until consciousness is regained. The observers seem to be warranted, therefore, in the conclusion that "the action is due directly or indirectly to its influence on the nervous system, . . . mainly on the spinal cord, but also on the brain and motor nerves." Death is due to paralysis of the respiration, and as quite a number of accidents have been reported from the employment of this drug, a repetition of Semnola's words at the Paris Congress in 1889 will not be inappropriate. Doubtless many physicians would willingly emphasize his remark, that "antithermics act like poisons; they afford a sort of temporary relief, but at the expense of the patient's strength and early recovery."

When using antipyrin medicinally, care must be taken to avoid incompatibles; thus, when chloral and antipyrin are united in a mixture an oily liquid is formed, and gradually crystals are deposited. This substance has been investigated by Herr Reuter,[1] who states that it is therapeutically inert, although he has given it the following technical name: trichloraldehydphenyldimethylpyrazol. In the same journal for May, 1890, the incompatibility of antipyrin with carbolic acid, confirmed by Tarday, was noted. A solution of carbolic acid added to antipyrin separates, after some hours, into two layers, the upper layer containing no carbolic acid, but having the taste of antipyrin. The lower layer had a piquant taste, a faint rosecolor, and slight odor of phenol, with a specific gravity of 1.13. Soluble in alcohol and ether, but insoluble in water, and neutral in reaction.

Antipyrin possesses the property of increasing the solubility of certain salts of quinine. When to the hydrochlorate of quinine a small quantity of antipyrin is added, it will become readily soluble in a comparatively small quantity of water, while it has the advantage of remaining unaltered. The almost insoluble valerianate of quinine may be prepared in a similar manner; one part of the valerianate combined with from one to one and a half part of antipyrin will readily dissolve in double the weight of water at 62° C. In view of these facts it has been suggested that this combination may find a practical application in the preparation, without the addition of an acid, of a stable solution of quinine for hypodermatic use. A combination has been suggested with salicylic acid, under the name of salypyrin, but at present no therapeutical indications have been mentioned. When combined with sweet spirits of nitre, antipyrin causes a greenish-blue precipitate, called iso-nitroso-antipyrin, but physiological investigations show that this product is harmless. The precipitate may be avoided by the addition of a small quantity of water of ammonia to the nitre before combining it with the antipyrin. About one drop to the half ounce of sweet spirits of nitre will generally be sufficient, and if the bottle is kept well stoppered no precipitate will take place for months. The alkali neutralizes the nitrous acid of the nitre, thus preventing its combination with the antipyrin.

Elimination takes place chiefly by the kidneys, and therefore it must be used with caution where we have present organic changes in these organs.

The general action of antipyrin is that of an antipyretic and analgesic, although it is not now so highly regarded for its antithermic properties as when first introduced. It has within a comparatively recent period been gaining a reputation for the relief of neuralgia and other acute affections, which apparently in the main seem to be due to the condition of the blood, the general debilitated condition of chronic neuritis, or other derangements of the system whose causes are not well understood. It should, however, be borne in mind that the disorders are for the most part symptomatic, and that the relief afforded by antipyrin is but palliative. A word should be added concerning its antipyretic properties, and its comparative value in this direction. This subject has been studied by Major Crombie,[1] who regards antipyrin as entitled to the first place, although phenacetin, he says, is a close second; in point of safety, however, phenacetin is the best, because in his experience with these agents in intermittent, enteric, and simple continued fever, and acute tuberculous pneumonia, it did not produce subnormal temperature, nor did it cause collapse. The effect is more prompt than when either antifebrin or phenacetin is given, although the temperature reduced by phenacetin is longer in rising again than after a reduction by antipyrin. Crombie regards the sweating which follows the use of all these drugs as an objectionable feature, and in this respect he thinks they are all alike. Antipyrin, we may conclude from the foregoing, is the remedy to use when the hyperpyrexia becomes dangerous, while phenacetin and antifebrin in small doses may be used when the object is to reduce a moderately high temperature, and at the same time maintaining a lowered temperature.

Reference has already been made to the action of the drug upon the nervous system. The conductivity of the motor nerves is first destroyed, and following immediately upon this they lose their irritability. Observations with relation to the influence of antipyrin on the normal circulation are somewhat contradictory, some claiming that blood-pressure is not increased, while others assert the contrary, insisting that blood-pressure is raised, the frequency and force of the heart being increased. The facts appear to be about as follows: The first effect upon the circulation, which is comparatively transient, is to increase the pulse-rate, which creates a subjective sensation of warmth. This condition is succeeded by more or less free perspiration, lessened frequency of pulse, and a sense of chilliness, together with pallor, takes place, with an actual fall of temperature of from one to three, or even five degrees. The decline in body-heat begins usually within half an hour, and may continue two to five hours, or even longer, but with the exception of heat-fever this decline is not maintained unless the drug be continued. No influence is exerted upon normal temperature, which leads to the conclusion that its exhibition is attended with less danger than some other members of the phenol group, at least when large doses are given.

It has been noted that the action of antipyrin upon the temperature is similar to that of picrotoxin; heat favors the activity of the drug, while cold hinders the effect. In the case of lethal doses being taken, therefore, followed by paralytic symptoms, cold to the surface, in the shape of ice-bags, will arrest its power, and probably prevent a fatal termination—an important item to be borne in mind in the treatment of heat-fever. Professor Cash says it is not a specific through its influence upon the temperature, and he recommends but small doses—one grain three times daily—to reduce hyperpyrexia. While this dose is very minute, as we understand it, no doubt good will follow its employment in small doses at short intervals. A word should be added to the effect that antipyrin is not indicated in scarlet fever, diphtheria, and eruptive diseases as a class, measles excepted. The line is drawn at measles owing to the fact that as it is usually a light disease the action of the drug upon the skin would be desirable, while the other disorders are more tedious in their course, and consequently the depressing effects of the antipyrin would be objectionable.

Failure of respiration is doubtless the cause of death from the long-continued exhibition of antipyrin, an observation which may possibly throw some light upon the exceptionally great mortality attending the influenza which appeared in this country about a year ago. There can be no doubt in the minds of many observing physicians that deaths could be traced directly to

[1] Pharmaceutical Journal and Transactions, February, 1890.

[1] Practitioner, October, 1889.

the use of this drug, sometimes ordered by the physician, but too frequently taken on the recommendation of some kind (?) friend.

The curious circumstance connected with the action of the drug on muscular structure has already been noted; during anæsthesia no effect is noticeable from lethal doses.

The effect of antipyrin upon the digestive apparatus, the blood, and secretions must not be overlooked. Apparently antipyrin does not act as an irritant to the stomach, but in small doses, not too frequently repeated, it rather aids digestion, possibly through its influence over micro-organisms, although occasionally vomiting is produced, when it must be given subcutaneously or by enema. Upon the blood important changes are effected; the hæmatin being separated and the corpuscles altered in form, the blood assumes a chocolate hue. This action is much like that of antifebrin, large doses destroying the oxygen-carrying capacity of the red corpuscles.

Antipyrin affects the entire genito-urinary tract. The urinary secretion is markedly affected; the elimination of nitrogenous material is reduced both in health and disease, while the inorganic salts are diminished. The excretion of urea is also diminished, as well as the urinary water, and, as previously noted, it must be used with caution where organic renal changes are present. The action upon the uterus is such that clinicians are not favorable to its employment during the menstrual flow, and it must be given with caution to nursing women, as it has been known to arrest the secretion of milk.

A symptom not infrequently noted after the exhibition of antipyrin is the rash which appears on the skin. It is similar to that which we see in attacks of measles, and consists of circular rose-colored spots, which show a brown pigmentation on pressure. A case of poisoning from seven and one-half grains has been reported (MEDICAL RECORD, 1887), which was attended with gastric pain, and followed in a few minutes by an urticaria-like eruption over the body, and great itching. The symptoms were caused to disappear by the subcutaneous use of $\frac{1}{60}$ grain of atropine (Whitehouse). The antiglycogenic influence of antipyrin has induced practitioners to recommend it in the treatment of diabetes; but it is doubtful if such treatment can be more than palliative, as the liver will demand other treatment to restore its integrity.

Therapeutics.—While it was intimated in the beginning of this paper that antipyrin was losing its position as an antithermic, it does not follow that the drug is losing its popularity, or that its employment will be discontinued. On the contrary, a multiplicity of uses have been found for this remedy aside from an antipyretic, and an effort will be made in the following remarks to indicate, in a connected manner, the various classes of disorders in which it may be used with prospects of success.

First in order will come the study of antipyrin in the treatment of spasmodic affections. Asthma is the first of this class demanding our attention. Whether in the moist or dry form, antipyrin will usually relieve the first attack, if given in doses ranging from ten to twenty grains, but after the disease has been some time under this treatment the remedy appears to lose its effect, and no benefit can be noticed. Unfortunately it does not diminish the frequency of the attacks, and occasionally it does harm by increasing the severity of subsequent attacks. The *rationale* is extremely simple; the influence of the drug upon the blood obtunds the sensory nerves, and succeeding upon this we have a changed condition of the blood, which favors the accumulation of carbonic acid. The advantages as well as the disadvantages of antipyrin in this disease will be apparent; while it may be used as an expedient in the emergency, when the nitrites, trinitrin, and oxygen inhalations are not at hand, it will be of no permanent benefit.

In the treatment of whooping-cough in the early stages antipyrin must be accepted as a remedy of undoubted value, and a very large number of cases have been reported in current medical literature. Guaita thinks possibly it may possess some inhibitory action upon the nervous system, and in addition antiseptic properties; but it will be apparent that the influence must be due to its effect upon the blood, and indirectly through the nervous system. For a child five years of age the dose should not exceed four grains, at intervals of four hours, and care must be taken that cyanosis does not appear, and the action of the heart and respiration should be closely watched to prevent collapse. In the case of much irritability of the stomach a minute quantity of cocaine may be added to the treatment, and along with this we might suggest the use of amber-oil as a counter-irritant to the spine, and small doses of calcium sulphide. These precautionary measures seem to be warranted from the fact that Tuczek reported the case of a boy,[1] who had taken the drug for a considerable period to allay the paroxysms of whooping-cough, when, at the expiration of three weeks, he was attacked with vomiting, and passed into a somnolence ending in deep sleep followed by epileptoid spasms — sometimes general, sometimes unilateral — accompanied by grinding of the teeth and jactitation, arythmia of the cardiac beat, and dilatation of the pupils.

In using antipyrin for the relief of renal spasm due to the presence of calculi, Huchard discovered that it possessed curative properties. Fifteen grains daily for some weeks will cause the disappearance of sand and uric acid crystals from the urine. The following is the formula of Schweig, of Carlsruhe:

℞. Antipyrinæ ..... gr. lx.
Sodii bicarbonas ..... gr. xij.
M. et ft. chartulæ, No. vi. Sig.: Take one powder after meals.

Although antipyrin is not usually indicated during the menstrual flow, owing to its effect upon the nervous system, which, as we know, is decidedly affected during that period, it has been employed successfully for the relief of menstrual colic. The dose recommended seems large—thirty grains, by enema—but no harmful results have followed when a glass of wine has been given to prevent collapse. This amount, it is said, can be repeated at the expiration of twelve hours should there be a demand, but its continuous use would be contraindicated.

The treatment of chorea, which is so often tedious and vexatious, will sometimes readily yield to antipyrin, whether simple or that dependent upon a rheumatic diathesis. For a child five years of age, after several small doses have been used to determine the tolerance for the drug, seven and one-half grains may be given three times daily. The following formula will be found useful:

℞. Antipyrinæ ..... ʒ iij.
Syr. auranii cort. ..... fl ʒ ij.
M. Sig.: One teaspoonful in water three times daily.

The action of the drug is manifested in the treatment of laryngismus stridulus. This is occasionally met with in very young children, and in such cases a small dose at short intervals will be indicated. The dose should not exceed one grain for each year of age, so that a child two years old would receive two grains every two hours until relief was obtained, unless there arose counter-indications. The drug has been recommended for the treatment of epilepsy, but the results so far have been unsatisfactory, large doses being necessary, and further, these patients suffer from more severe attacks after the use of the drug. Several reports have appeared regarding the use of antipyrin by enema in doses of thirty grains to overcome the pains of labor, and it is claimed that relief is afforded, and that there is no arrest of the expulsive efforts of the parturient womb. In view of the sudden dangers from the incautious use of the drug, however, I am inclined to doubt the advisability of this practice, and would suggest an anæsthetic instead.

When using antipyrin to overcome hyperpyrexia it seems to carry with it certain undefinable yet appreciable

[1] British Medical Journal, 1889.

anodyne and hypnotic properties, and may be used successfully in various neuroses, especially sciatica and other painful affections, presumably of rheumatic origin, as hemicrania, supra-orbital neuralgia, and in that form of insomnia due to "nervousness;" but it should be added that it will be found more especially valuable when these affections are associated with neuritis. There are diseases in which are present slight indications of spasm, and the value of antipyrin in this class of cases has been abundantly proven.

A number of prominent observers have within a year past given some attention to the employment of antipyrin in the treatment of diabetes mellitus, and the results obtained are such as to merit a favorable opinion of the drug in properly selected cases. Among those who have indorsed antipyrin in this affection may be mentioned M. Germain Sée, who, while administering antipyrin to a diabetic patient for neuralgia, was surprised to notice that the sugar entirely disappeared from the urine. Huchard has also used the drug with good results in polyuria, and also Dujardin-Beaumetz and M. Panas, the dose recommended being forty-five grains daily. The class of cases in which this treatment will answer best includes elderly persons and those who are comparatively robust, and in such cases a more liberal dietary may be permitted than is usually allowed diabetics. Whether warranted or not, the assumption has been advanced by those who have studied the matter, that the good effects following the use of antipyrin are due to its sedative action on the body, and that it is similar in this respect to opium and its derivatives. My own impression is that the sedative action of the drug is due to the changes taking place in the blood, and therefore my conclusion is, that antipyrin exercises a favorable influence in the disease under discussion owing to the changes in the blood, and the influence which these changes produce upon the nervous system.

Professor Sée believes that the dietary should include small quantities of fresh bread as well as some boiled potatoes, daily, in order to satisfy the cravings of the patient for carbohydrates. It is doubtful if antipyrin can cure glycosuria, although it doubtless may have a decided influence for a time on the excretion of glucose, and the subject is worthy of further study.

The treatment of sciatica, so often troublesome, will be greatly simplified by the judicious employment of antipyrin, and when we have a suspicion of a malarial element, the drug may be combined with equal parts of quinine, say seven and one-half grains of each three times daily. The suggestion may be advanced here that sciatica is a disease often composed of two factors, rheumatism and malaria, which will account for the good effects following the use of the combination named above, although either drug will serve to allay the paroxysms. Of course, much depends upon the condition of the system. Professor Cash says, no doubt it reduces the temperature in rheumatism, but does not shorten the disease, nor does it have any tendency to prevent a recurrence or the appearance of cardiac complications.

There is some question as to the advisability of giving antipyrin in pneumonia. Dr. H. G. Beyer has contributed an article on this topic, with an account of two cases,[1] and although the treatment included the use of morphine hypodermatically, he is inclined to believe that antipyrin had a favorable influence upon the course of the disease. For my own part, I cannot see that antipyrin will do more than relieve the pain, while it will certainly, if long continued, have a tendency to weaken the action of the heart. It may, however, have a favorable action upon the circulation, as my friend, Dr. E. T. Sabal, of Jacksonville, Fla., tells me that he has witnessed remarkably prompt results from the exhibition of comparatively small doses of antipyrin in pulmonary hemorrhage. In both instances the hemorrhage, which was very profuse and alarming, was arrested almost immediately, and he is disposed to think that it was something more than a mere coincidence.

[1] Medical News, June 15, 1889.

The use of the drug has been referred to in the treatment of headaches. It remains to be added that the sthenic cases are those most benefited, as it would be injudicious to use it for any great length of time where the vital powers are depressed from malnutrition.

Topically, antipyrin has been used as an insufflation for the relief of catarrhal affections of the upper air-passages, and may be employed in the form of enema to relieve the painful sensation produced by hæmorrhoids; but we have other more suitable remedies for both affections. An instance is recorded in which antipyrin was used by inhalation (1 to 20 of water), for the relief of hæmatemesis, and succeeded after a number of other remedies had failed.

The subcutaneous use of antipyrin has not thus far been practised very extensively, although various formulæ have been suggested. Antipyrin and ergot, it seems, would be incompatible when used together, although there might be indications for both drugs, and given at separate intervals much benefit might be derived from the combination. It might be advisable to combine with the antipyrin, hypodermatically, a small quantity of cocaine. As stated previously in this paper, antipyrin and quinine may be so prepared that they can be used subcutaneously to good advantage.

In conclusion, it is to be remarked that while antipyrin has met with extensive use, and has been employed successfully in the treatment of many and various affections, it is a drug which ought to be used with the greatest caution, especially when ordered for a patient for the first time. The tolerance of the patient should be studied before a large dose is administered, and care is necessary that the drug be not too long continued. The treatment of diseased conditions by antipyrin is not curative in the true sense of the term, and when too much dependence is placed upon it, the convalescence is prolonged, owing to the influence which the drug has upon nutrition.

1910 Arch Street.

BALNEO-THERAPEUTICS AND MECHANO-THERAPEUTICS APPLIED TO THE TREATMENT OF CHRONIC HEART DISEASE.

By THEODOR SCHOTT, M.D.,

Bad-Nauheim, Germany.

This essay is, in brief, a *résumé* of observations and experiences made in the course of fourteen years, during which time I have had occasion to observe and treat twenty-seven hundred cases of cardiac disease. At the outset I would beg to ask attention to a recapitulation of the labors of the late Dr. A. Schott, who, with myself, gradually developed the plan I have in recent years applied to this class of cases. In 1872 Beneke called attention to a series of fifty cases, which showed that treatment by saline baths not only prevented recurrences of attacks of acute articular rheumatism, or increased the intervals between attacks, but that recent endocardiac deposits and changes, such as are the complications and sequelæ of acute articular rheumatism, were absorbed to a greater or less extent. It was this that induced my brother and myself to apply this form of treatment to that more numerous class of cases, chronic endocarditis.

The special object of this paper is less to attract attention to Bad-Nauheim as a health-resort for this class of cases—for I appreciate only too well that, to the great majority of cases, absence from home and travel are impossible—but rather, by offering minute and carefully detailed directions as to both artificially prepared baths and gymnastics, to enable the practitioner to apply the treatment himself, and thus to obtain the same effects, if not in their entirety, at least to a gratifying extent.

It had long been known that baths containing salts and carbonic acid retarded the pulse-rate, yet no value was set upon this until Dr. A. Schott and myself had called at-

tention to the fact that these baths, as well as gymnastics, might fairly be considered as cardiac tonics, and that they derived their importance from their tendency to produce cardiac hypertrophy, and were, indeed, most important means of reaching the heart-muscle, the condition of which we considered the key to the treatment of cardiac disease. To a large series of cases we then applied the treatment by baths, combined with light gymnastics, which latter we replaced later with slight ascents of moderately inclined hillsides, following the suggestions of the great Stokes. Marked improvement followed in many cases, and complete cessation of murmur in a satisfactory number. Thus, both the baths and exercise were cardiac stimulants, urging the heart-muscle to renewed vigor and overcoming the cardiac dilatation, which was the principal thing to be overcome. (I do not here refer to *compensatory* dilatation, which requires no treatment.) A mere reference to the various essays which contain the result of our theoretical labors, in confirmation of the above practical results, will suffice at this present moment, and although what we are to say seems almost self-evident, its recognition has only been possible after a long and large experience, coupled with most devoted, self-sacrificing scientific activity. And although these results have been obtained at the natural baths of Nauheim, yet I am convinced, by many experiences, that the identical results may be achieved by artificially prepared baths. In all cases it is essential that the patient be examined before, during, and after the bath and exercise, for the exact effect cannot be otherwise gauged; and just as in other diseases the same treatment will not yield the same result in similar cases, so in this treatment much harm may be done when applied to improper cases or in an improper manner.

A. The Treatment by Baths.—If any sign of loss of compensation be present, it is best to begin with a one to one and a half per cent. solution of chloride of sodium (NaCl) to which from one to one and a half pint per thousand of chloride of calcium (CaCl) is added. The duration of the first bath should not extend beyond ten minutes, the commencing temperature should be from 92° to 93° F., and should not go below 88° F. during the first week. Special care should be taken with anæmic persons, and others with poor circulation, who feel cold easily. Equal caution should be used with rheumatics, not to use too high a temperature, never going beyond 95° F. For, useful as the application of warm baths and douches may be in relieving pain and reducing swelling, the tonic effect upon the heart is lost in an equal degree when applied to the latter group of cases. Instead of warmer baths, use those which are cooler and of shorter duration. If the patient remain quiet, it is permissible for him to feel cool for the first half-minute, after which he ought to feel the reaction to a grateful warming sensation; if not, the temperature has been too low, and the bath should be made warmer. No second chilly sensation should follow, for this is evidence that the bath has been too long continued, at least for this particular temperature, and the patient should leave the bath at once. During the beginning of a course of treatment, intermissions should occur at stated intervals. At the outset the bath should be omitted every other day, then every third day, and finally every fourth day. Later the bath is increased in all directions; in its chloride of sodium increasing it to two to three per cent., the chloride of calcium being increased to one-half to one per cent. Next, with the latter percentage of salts a small quantity of carbonic acid gas (CO_2) is added (equivalent to the Nauheim thermal bath); and last of all to the bath with a large quantity of carbonic acid (the so-called Nauheim bubbling-spring bath). Coincidently, we diminish the temperature to 88° to 85° F., even exceptionally to 80 F., and increase the duration to twenty and twenty-five minutes. It is not possible, however, to imitate the strongest of the so-called Nauheim aërated bubbling spring bath (Sprudelstrombad).

In the other artificial baths it is not difficult to supply the carbonic acid by using bicarbonate of sodium and hydrochloric acid. Dissolve the sodium salt with the other salts in the bath, and then put in a vial containing the acid, allowing it to diffuse slowly from out of the uncorked vial; or else mix the acid with the bath, and carbonic acid will continue being developed for half an hour and longer.

If you take a diluted solution containing forty-two per cent. of hydrochloric acid, you use equal parts of solution and bicarbonate of soda; if the solution be weaker, you must add more of the latter. For a weak carbonic acid bath from 100 to 150 grammes of each will do, until you finally have increased it to from 1,000 to 1,500 grammes.

Now, if in the course of the bath treatment, the effect upon the heart, pulse, respiration, and general well being is favorable, be careful not to push the treatment to the extreme, for the bath is laborious to the body, and the slightest excess may constitute overstrain and be followed by bad consequences.

B. Gymnastic Treatment.—In resorting to gymnastics we make use of two varieties, passive and active; or more properly speaking, in the former case movements of resistance, the muscular strength of another controlling the extent of the movement of the patient; in the latter, the patient himself calls into action antagonistic muscles and thus limits his own movements—self-limited movements. The following rules, among others, should be applied in resorting to them: Every single exercise must be made so slowly, and in movements of resistance the counter-pressure must be so carefully gauged, that the patient is able to breathe quietly throughout the entire movement. This is best secured and all muscle-tire guarded against by changing and constantly calling into action new sets of muscles, and leaving an interval of rest after each new exercise. The gymnast is instructed to control the respiration by observing the mouth and alæ nasi, noting the pulse as well, and still further regulating the resistance to such an extent that the patient retains the mastery. In order to maintain this latter, if you are dealing with seriously ill patients, every individual exercise should be divided up into its component movements, allowing the extremity called into action to rest in the hands of the gymnast meanwhile. Still further, all movements must be completely carried out, and must not be allowed to falter or remain unfinished.

The movements to be applied to the muscles of the extremities and joints are so suggestively evident that it is not necessary to enter into details about them here. I would call attention to the fact that ordinary intelligence and zeal will enable the physician to make a gymnast of some one member of the family, and thus make this treatment more accessible and less onerous in many ways to the patient. The gymnast must not seize the entire circumference of the joint, lest he limit the movements rather than favor them. If any exercise have been undertaken too quickly or with too much resistance, which increased rapidity of pulse and respiration will show, the next exercise must be delayed until everything has been restored to rest. Later it is highly desirable to have the patient make use of the self-limiting exercises, which have the advantage that a third person is not needed. Still it is considered advantageous to resort to the passive exercise for several weeks at the beginning of treatment. As a finale in gymnastic treatment, resort is to be had to mountain, or rather hillside, climbing, the most severe form of exercise, after the heart-muscle has been sufficiently restored to tone.

Contrary to Oertel's claim, as I have remarked in other papers upon the subject, I do not consider hillside climbing at the outset as at all proper in the resort to gymnastic treatment, but rather at the end of it, if we would guard against probable dangers, which under some circumstances may threaten the life of the patient; for climbing requires an amount of over-exertion upon the

part of the heart-muscle which it is not equal to at the outset. Still further, other methods of treatment (medicinal agents, baths, gymnastics, etc.) should be used to strengthen the heart until it can undertake this over-exertion without any risk. The physician should, however, not rest satisfied until he has carried the patient up to the point where mountain climbing may be undertaken without danger, as I have been enabled to do in a considerable number of cases. I have seen patients, after the completion of the cure at Nauheim, including the gymnastic treatment, make extensive tours through the Alps—yes, even (and I have the corroboration of the family physicians of the patients) ascending Mont Blanc and Monte Rosa—without having been troubled with any inconvenience as far as the heart was concerned.

Mode of Action and Results of the Balneo-therapeutical and Gymnastic or Mechano-therapeutical Treatment.—In a few words I wish to explain the mechanism by which this treatment accomplishes its purpose. Whether time may call into question the following theory or not, the facts—that is, the favorable results of both forms of treatment—must remain unimpeached. Irrespective of the hundreds of cases of improvement and cure which I have seen in Nauheim, and which I have published, other authors (Scholz, Mayer, Schmid, etc.) have in their own experience confirmed the correctness of these utterances.

As already stated, we increase the weakened action of the heart, giving tone to the cardiac muscle, and enable it to empty itself of its excessive quantity of blood by reinforcing its systolic contractions. It has been demonstrated, by myself and others, that by imbibition the bath incites the sensory tegumentary nerve filaments to cause more forcible cardiac contractions. Gymnastics produce the same result through the motor tracts. We thus, in a majority of cases, note the following as a result of treatment by both means: At first the tendency to lateral dilatation disappears, particularly in the direction of the right heart, though that in the opposite direction becomes appreciably less in the course of treatment; the most difficult problem, however, is that we have in overcoming the yielding in the longitudinal axis; yet even in this direction we can in time, by palpation and percussion as well as by the visible rise in the apex-beat, recognize that retraction on the part of the left heart takes place. By auscultation we frequently observe a murmur passing over into a reduplicated heart sound and finally succeeded by the normal sound, thus proving that no organic valvular change existed, but that the signs of a relative insufficiency were alone present. Again, in other cases in which the heart-sounds were hardly appreciable on account of the weakened cardiac muscle, murmurs become appreciable through the strengthened action of the heart. *Pari passu* with these objective phenomena, existing dyspnœa disappears, an arhythmical pulse becomes regular, its frequency diminishes, as I have seen in innumerable instances—for example, sinking below 100 from over 120, and to 72 from over 90. Measured by the sphygmomanometer (Basch's), the arterial pressure rises from 20, 30, and 40 mm. of the mercurial gauge. Hyperæmia of the liver frequently disappears, sometimes contracting one or two finger-breadths after a warm saline bath or gymnastic treatment; renal congestion is diminished and an increased diuresis follows upon scanty urination. The general well-being of the patient is correspondingly restored, his ability to walk increases, bright thoughts follow mental depression—in short, the entire organism is improved in all directions. In comparison with digitalis, the bath and gymnastic treatment have no hurtful action, and excel the former by the greater permanency of their results.

Exclusive of two contra indications to this treatment (1, aortic aneurism, and 2, marked arterio-sclerosis, moderate sclerosis is not a contra-indication for the bath treatment), I have seen no cases of cardiac disease—whether congenital or acquired, whether idiopathic, such as nervous or functional heart disease, weakened heart, fatty heart, myocarditic disease, up to the most complicated or most advanced cases of loss of compensation accompanying organic valvular disease—in which I have not seen at least temporary, if not more or less permanent, improvement.

In conclusion, attention is to be called to the fact that by means of these methods of treatment a considerable number of complications, or more properly speaking diseases, which stand in an etiological relation to cardiac disease can be improved. We have already referred to rheumatic disorders; in chronic renal disease the quantity of albumin is frequently markedly decreased by the bath treatment, occasionally even disappearing entirely (as was evidenced, among others, in two cases sent me by Dr. Herman Webber, of London). Furthermore, by the addition of gymnastics, combined with general massage, cases of diabetes have been improved. In pelvic plethora, combined with constipation, the use of the "Karlsbrunnen" spring water, or curative spring water, is joined to the methods of treatment referred to. The former mineral water resembles the "Elizabeth" spring of Homburg, the latter that of the "Ragoczy" of Kissingen, these two acting identically upon proper dilution.

In cases of gout the use of the "Ludwigsquelle" water, which contains lithia and bicarbonate of sodium, is followed by marked improvement.[1] It is hardly within the province of this paper to refer to the well-merited reputation which Bad-Nauheim has enjoyed for many years, for the treatment of neurasthenia and acute and chronic spinal cord lesions (to which Erb can so abundantly testify), and the resulting improvement and permanent relief brought about, in part by the treatment itself, as well as by the pure air, the invigorating influence of the surrounding woods, and dry sandy soil.

In conclusion, while recognizing the many advantages which a stay at Bad-Nauheim has for the patient, to wit—absence from home cares and responsibilities; the elevation, and the healthful and invigorating surroundings and tempting walks; the accuracy with which the strength and constitution of the different baths may be gauged (Nauheim by its multiplicity of springs of varying composition, being more than ordinarily favored); the small size of the village, enabling the physician to see his cases daily once or more times before, during (if necessary), and after the bath, at the residence of the patient or doctor—I none the less hope that for the great masses to whom absence from home is impossible the resort to the treatment by artificial means, as above described, may be had, and in the results confirm that by the use of carbonated thermal-saline baths, artificial as well as natural, as also, by the added use of gymnastics or mechano-therapeutics, the therapeutics of chronic heart disease have received important additions.

Whenever you are asked if you have heard of Dr. Blank you can always answer conscientiously in the affirmative if you have listened to the question.

[1] Among others, I refer to cases reported by Dr. H. N. Heineman, in an article upon "Treatment of Cardiac Disease," published in the Medical Record, April, 1890.

THE DIFFERENT PHYSIOLOGICAL AND THERAPEUTICAL PROPERTIES OF THE INDUCED CURRENTS OF ELECTRICITY,

With Especial Reference to Bipolar Faradization.[1]

By A. D. ROCKWELL, M.D.,

NEW YORK.

When Duchenne first called the attention of the profession to his method of localized electrization, it will be remembered that he practically excluded the galvanic current from consideration and confined his experiments almost entirely to the faradic. Remak, on the contrary, and many of his followers, advocated the galvanic current mainly, and for a time a fierce and unreasonable controversy was carried on between the two. In the light of our present knowledge of the different forms of electricity, it would appear little less than childish to champion one form to the exclusion of the others, since there are few diseases for which electricity is indicated where either current might not, under varying conditions, prove of service, and few methods of application where both currents may not be utilized. There is one method, however —the bipolar—which seems to be a special field for the faradic current, and in which the use of the galvanic current is seldom desirable.

By bipolar faradization is meant the localization of the faradic current by means of a single electrode, and the method is confined for the most part to internal treatment, *i.e.*, to the treatment of the vagina, the uterus, the rectum, and the bladder. In order, however, to any satisfactory appreciation of this subject, so much of electro-physics as bears directly upon the topic under consideration must at least be briefly reviewed. For a few moments, therefore, I bespeak your patient attention while I consider a number of facts in regard to the physical and physiological action of the induction coils, some of which appear to be a veritable *terra incognita*, even to those who make much use of electricity in medicine. It seems hardly necessary for me to state the simple fact, that most induction apparatuses are composed of two distinct and separate coils, one of which, called the primary, is made of thick and comparatively short wire, while the other and outer coil consists of wire that is thin and very long. Every possessor of a faradic battery appreciates also that there is a great difference in the character of the current proceeding from these coils. From the primary coil, as the electrodes are held in the hand, or placed on any portion of the external surface of the body, the current seems comparatively mild and inefficient, while the current from the secondary coil acts with far greater vigor. It not only more vigorously contracts muscle, but excites the cutaneous sensibility more acutely and the retina more vividly than the current from the primary coil. Apply, however, this current (primary coil) directly to the bladder, the rectum, the vagina, and especially to the involuntary muscular fibres of the uterus, and a very remarkable and interesting change is observed. It will be found that the current from the first helix acts with astonishing and most unexpected vigor on both sensory and motor parts. We are accustomed to say that the long thin wire yields a current of tension, and the short thick wire a current of quantity, and the more vigorous action of the second helix, when application is made externally, is commonly attributed to its superior tension; but the immediate and astounding change in the physiological effects of the two currents when applied directly to the internal organs of the body cannot be altogether explained in this way. Studying the phenomena of induction as produced by the initial voltaic current alone, without the intervention of magnetic force, Duchenne long ago conclusively proved that the difference in the length and thickness of the wires of the two helices did not alone explain the different action of the two currents on the sensibility.[1]

We may say that the currents have elective properties, or properties special to each, but the reciprocal relations between the nervous system and the action of electricity are not yet sufficiently understood to offer a satisfactory explanation of the interesting fact that in external local faradization the current of tension is the most effective, both as to objective and subjective symptoms, while in internal local faradization the so-called current of quantity acts most vigorously.

If instead of using the unipolar method—one pole internally and the other externally—we use a bipolar electrode, and in this way treat the vagina, the uterus, or the rectum, the current from the first helix will act with greatly increased vigor, an increase that cannot be altogether accounted for by the decreased resistance that is necessarily offered.

Although around the primary coil of an ordinary induction apparatus extra and distinct coils of finer wire up to the number of nine can be wound, the current from each successive coil becomes weaker and weaker, and experience has shown that for all practical purposes there is need for but two helices, or at most three, that yield the primary and secondary induced currents. This apparatus, we term the separate-coil apparatus, to distinguish it from another combination of helices, termed the continuous coil, and it is the current from these two distinct coils of the separate-coil apparatus to which reference is always made in the consideration of bipolar faradization. In this paper, however, I shall speak of bipolar faradization in connection only with the continuous coil helix, the efficiency of which over the other form is very great. While in the ordinary separate-coil machine with which Duchenne carried on his original series of experiments, and with which Apostoli and others practise the bipolar method, we are limited to two currents—the primary induced and the secondary pure induced—we obtain from the continuous apparatus many distinct manifestations of the induction current, four of which, at least, differ so widely in their physical, physiological, and therapeutical properties as to render it a matter of the utmost importance that we appreciate the fact that these currents cannot be applied indifferently in practice.[2]

Indeed, let one become but once convinced by personal experiment of the striking difference in the action of these four qualities of current on nerve and muscle, and he will hardly need the demonstration of clinical experience to convince him of their different therapeutical properties. The current from the primary, or first induction coil of the continuous coil apparatus corresponds very closely with the current from the primary coil of the separate or double-coil apparatus. The wire is short and thick, offering very little resistance to the passage of electricity, and so gives forth a current of little tension but large quantity, so called. When applied externally its appreciable influence is very slight. Its tension is so low that it overcomes with exceeding difficulty the resistance of the skin that must be encountered in all external applications. Its reflex as well as direct influence is therefore very slight, and it only moderately excites cutaneous sensibility.

It acts with considerable chemical power, readily burning steel or iron, as manifested by the bright deflagrating spark given forth. It will electroplate and electrolyze to a degree not attainable with the other induction coils either alone or in combination. The important practical point, however, in connection with this current, is the extraordinary increase in energy that is manifested when application is made to parts within the body. When applied to the rectum, the vagina, or the uterus, not only are the contractions pronounced, by a strength of current insufficient to produce any observable effect when applied

[1] Read before the New York County Medical Society, December 22, 1890.

[1] Localized Electrization, p. 29.

[2] A description of these coils will be found in Beard and Rockwell's Medical and Surgical Electricity, sixth edition, p. 292. William Wood & Co., Publishers.

externally, but may easily be made exceedingly painful. It may be here remarked that the testes also are far more acutely sensitive to this current than to the currents of pure induction.

Far more severe in its influence, however, is the second current of the series—that proceeding from the primary and second coils of the combination. Externally applied it is comparatively weak, although far stronger than the other; but when applied by the bipolar method to the uterus or vagina, its extraordinary action on motor and sensory parts will hardly be credited without actual demonstration of the fact. It is the easiest thing in the world to demonstrate this fact unwittingly, to the injury of the patient and to the operator's mortification. This is what may very readily occur. An intra-vaginal or intra-uterine application is being made with the current of tension. The patient complains of an uncomfortable sensation, which may or may not be due to the action of the current, and you shift the slide so as to exchange the current of great for one of lesser tension, which, according to all the experiences of external application, is infinitely weaker. Instantly a shock is occasioned, associated with the acutest pain and the most rigid contractions, that astonishes yourself and terrifies your patient, a mishap which I have known in more than one instance to excite neuralgia and other severe nervous symptoms of a distressing and more or less permanent character.

The advantage of these first two currents of the series over the last two, presently to be described, lies almost wholly in the effects of their internal application, and especially by the bipolar method. Both currents, and especially the current from the combination of the primary and second induction coils, act as powerful muscular tonics when applied internally, and are capable of exciting contractions of the involuntary muscular fibres of the uterus of every degree of severity. For this reason it is invaluable in cases of post-partum hemorrhage, and must, it seems to me, prove far superior to ergot for its suppression, since it acts instantaneously, and with a force just sufficient to accomplish the object desired.

In the ordinary form of subinvolution the current from the primary and second induction coil is invaluable. Bipolar intra-uterine applications persistently repeated, and with a strength no greater than can be readily borne by the patient, will afford results so gratifying that no one who has once had experience in the method will wish to treat a case of subinvolution without its aid. In regard to the action of the primary induction coil, in its external application, I have, I am confident, observed certain effects worthy of citation.

Some cases of hyperæsthesia of the scalp and face, and not a few cases of pain of a true neuralgic type and superficial in character, are more readily relieved by this current than by any proceeding from the pure induction coils unassociated with the battery influence.

It is a difficult thing to explain many of the phenomena of electrophysics. We can state them and utilize them, and so render them of immense service in the arts and sciences. Many of the phenomena of electricity as related to physiology are equally unexplainable, but none the less do we utilize them in therapeutics. Why the current from the primary induction coil should manifest a superiority as stated above, it is impossible to say, without we ascribe it to that combination of the battery and inductive influence which it possesses in such perfection. The third current of the series—that proceeding from the primary and the second and third induction coils—is of unique quality so far as relates to its effects when applied externally. Like the primary coil it will electroplate, but unlike it, it will not burn steel or iron. The peculiarity of this combination of the coils is that the maximum of power to contract the muscular tissue when the application is made through the medium of the skin is here obtained. Each additional coil that is now attached simply gives a decreasing contractile power. Why the maximum of current-strength is reached in the combination of the primary with the second and third induction coils it is difficult to say, excepting as we ascribe it to the law of harmony or polarization that is brought about by properly conditioning the magnetic centre of the helix, the several coils composing the helix, and the battery influence acting upon the coils. This current, possessing less quantity, but far greater tension than the two preceding already considered, exerts by no means the same influence over the contractions and sensibility of the vagina, uterus, rectum, or bladder; but its energy of action in this direction is greatly superior to the fourth current of the series next to be described. To emphasize the advantages in bipolar faradization of this combination of helices over the separate form, mark the distinct and varied effects obtained from the first named. The current from the primary coil, although very weak when applied externally, exerts very positive effects upon both the sensory and motor nerves when applied internally. From the primary and second induction coil we obtain a current the effects of which are tenfold greater, and the utmost caution is called for in its application. Adding the third induction coil, the application still being internal, the sensory and motor effects are yet marked, although far less severe than the current from the preceding coils, but greatly in excess of the fourth and last current of the series. This current, for the production of which all four coils are necessary, is in many respects the most important, and has a range of usefulness wider than the others. Its action is pre eminently tonic and sedative.

The currents from the two preceding combinations of coils are exceedingly harsh, and so keen and cutting in character as to be absolutely painful if carelessly administered. This current, on the contrary, is always agreeable, or at least not painful, even when administered to the point of endurance.

Therefore in the operation of general faradization, when we desire to obtain the best constitutional tonic effects that electricity is capable of giving, we resort to this combination of the coils. While we cannot satisfactorily explain all the complex action of electricity on the tissues as it influences animal nutrition, the same may be said of the action of almost every other remedy. Who can explain why arsenic feeds the nervous system, why quinine breaks an attack of chills and fever, or how opium produces sleep and relieves pain, and who has entered into the mysteries of anæsthesia? Electricity in passing through the body modifies the nameless and numberless phenomena every moment going on in the living tissue, and as a resultant of its complex physical, chemical, and physiological action there is improved nutrition and increased development and growth.

For the production of such effects experience amply testifies to the superiority of the current under consideration to any of the others. For the relief, therefore, of that great army of symptoms that are so familiar and perplexing to those who have much to do with neurasthenic cases, there is nothing to be compared with it. Even the galvanic current, by the method of central galvanization, so important in its direct effects upon the central nervous system, falls short of the therapeutic results that follow through applications of general faradization.

When persistent failure follows endeavors along this line of electrization, the cause of failure must be attributed to hasty and faulty methods of administration. Even more marked is the difference in the action of this current of tension and the current of quantity in bipolar faradization of the rectum, vagina, and uterus. Its comparatively mild action on the motor and sensory nerves, coupled with its great power of overcoming resistance, render it, *par excellence*, the current for the relief of pain.

It is no exaggeration to say that in many cases of pain associated with uterine disorder it acts with almost magical effect. Herein lies the remarkableness of the phenomena associated with the action of the different induction currents—the apparently elective properties residing

in them, for, as indicated before, the difference in mere tension and quantity fails to offer an altogether satisfactory explanation.

While the currents from the first two coils act but feebly when applied externally, but with astonishing vigor when applied internally, the current of tension from the whole combination of coils acts with a vigor that is felt through all portions of the system when applied externally, yet when applied to the uterus through a bipolar electrode its action is but slightly felt, and is without disagreeable sensation. So tolerant, indeed, are the internal muscular organs of the body to the induced currents of tension that it is frequently a question of how to obtain a current of sufficient power from the batteries in ordinary use. Batteries that have been long in use and that are illy kept, while perhaps yielding a current of tension of sufficient strength for localized applications externally, are insufficient for bipolar applications. Even if at first the current is appreciably felt in the uterus, the sensitiveness soon subsides although its strength may have been very much increased, and both physician and patient may be in doubt as to whether the current is being received at all.

This phenomenon becomes prominently apparent in hysterical cases with which is associated excessive hyperæsthesia of the abdomen, and it has been no uncommon thing in my observation to treat women with the current of tension for the relief of the most acute surface abdominal hyperæsthesiæ, and at the close of a single *séance* to find the abdomen insusceptible to any ordinary manipulation. Far different is it with the current of quantity. Tolerance is not established, and what is painful in the beginning continues more or less painful throughout the treatment, and it frequently becomes necessary to decrease rather than to increase the current strength. To avoid the disagreeable shock, of which the patient invariably complains even when beginning the application with the minimum of current strength, a rheostat should be intercalated.

The main points that have been considered in this presentation may be thus summed up:

1. From the continuous-coil apparatus, owing to its combination of helices, the wires of which differ in thickness and length, proceed four qualities of current that vary in a most remarkable degree in all the properties of electricity—physical, physiological, and therapeutical.

2. That the variation is observed most markedly when applications are made internally to the vagina, uterus, rectum, or bladder, by the bipolar method.

3. From the primary or first induction coil we obtain a current of quantity that is barely perceptible externally, but internally, and especially by the bipolar method, acts with greatly increased efficiency.

4. From the combination of the primary and secondary induction coils we obtain a current of greater tension, but which still acts mildly when applied externally. Applied internally, however, its effects are far greater than the first coil, both in exciting the sensibility and contractility, and the utmost caution must be exercised in its use. In the same degree, also, it acts upon the vagina, rectum, bladder, and testes. This current is especially applicable in the treatment of enlargements of the uterus due to subinvolution, but is of little or no value when the enlargement is due to fibrous tissue. It is of especial value in post-partum hemorrhage, and from its power to excite the sensibility and contractility of the bladder and rectum it may be used with good effect when these organs are anæsthetic or suffer from diminished or lost contractility.

5. From a combination of the first, second, and third induction coils we obtain the maximum of power to excite both sensibility and contractility on the external surface of the body, each additional coil simply giving a decreasing power over sensation and contraction. Applied internally, however, it acts far less powerfully than either of the two previously named currents; but in the ordinary forms of paralysis of voluntary muscles it will more readily call forth contractions than the current from any other combination of coils.

6. From the first, second, third, and fourth induction coils combined, a current is obtained, differing from and superior to all the others in its sedative and general tonic effect upon the system at large. It neither acts upon the sensibility nor muscular contractility when applied externally as does the third current of the series, nor with a tenth or even a twentieth part of the acuteness when applied internally, that characterizes the second current of the series. For the purposes of general faradization, however, it is the only proper current to use, and for applications to the vagina and uterus, for the relief of many forms of pain, it possesses properties that are invaluable.

In the foregoing discussion I am fully conscious of having indulged in some reiteration, but it seemed to me necessary to a full appreciation of the important facts that have been stated.

To those who look upon electricity with indifference, and would relegate its use to ignorant attendants to be used as a placebo, instead of intelligently and conscientiously developing the subject for themselves, the statements here made may seem of little importance.

For those, however, who are more hospitable in thought, and will take the pains to master the principles of physics and the technique of electrical applications, I confidently predict a plentiful harvest of good results.

Progress of Medical Science.

The Use of Forceps in Breech Cases.—Dr. Fürst, of Graz, strongly recommends the use of forceps in delayed breech cases, in preference to the fillet or blunt hook. The forceps should have a large cephalic curve, and the points of the blades should come close together. Traction should be made only during the pains, and then the force of uterine contraction and the pressure of the soft parts will tend to prevent slipping of the blades. The instrument is used, therefore, simply to supplement an inefficient driving force.—*Archiv für Gynäkologie.*

Experimental Investigations with Tuberculous Milk.—Dr. Bang, of Copenhagen, has published in the *Deutsche Zeitschrift für Thiermedicin* some researches on tuberculous milk. From fifteen to thirty minims of milk from twenty-eight tuberculous cows with healthy udders were injected into the abdominal cavities of as many rabbits. The milk of only two cows proved infectious. The milk of eight highly tuberculous women produced no evidences of tuberculosis. Abscesses which occurred at the site of inoculation or in the abdominal cavity were not tubercular. Sweet and sour cream, obtained from tuberculous milk containing many bacilli proved virulent. Butter made from the milk (containing many bacilli) of a cow with advanced tuberculosis of the udder, injected into the peritoneum, produced severe tuberculosis. Feeding rabbits with such butter was followed by a like result. The use of butter obtained from tuberculous animals need not therefore be regarded as especially dangerous. The secretion of milk in cows with advanced tuberculosis—at best but slight, is permitted to cease entirely. Besides, such cows rarely supply tuberculous milk, from which by centrifugal action the bacilli are largely removed. Gerhardt has demonstrated that the danger of infection is in direct proportion to the number of bacilli. These experiments emphasize the necessity of paying careful attention to tuberculosis of the udder. Further investigation demonstrated that the bacilli or their spores are not deprived of their virulence by exposure to a temperature of 176° F., but that for this a temperature of 185° F. seems to suffice. A temperature of 212° F. is absolutely destructive of the bacilli. This statement as to the degree of heat applies to the tuberculous fluid, not to the bath. Two rabbits, fed with tuberculous

milk heated to 140°–149° F. showed signs of mild tuberculosis, while of six given the milk unboiled, all succumbed to typical tuberculosis. Rabbits which received milk heated to 158–167° F. remained absolutely free from infection. A rabbit, fed for seventeen days with unboiled tuberculous milk, which died accidentally, showed only tubercles in the lymphatic glands above the fauces—clinically the primary site of tuberculosis in cattle and swine. Dr. Bang considers it probable that a large proportion of tubercular (scrofulous) affections of the cervical glands in children owe their infection to tuberculous milk.

Scarlatina without Pyrexia.—Dr. Wertheimer reports a case of scarlatina occurring in a child, seven years of age, in whom, though the eruption was well marked, and the tonsils and tongue presented their characteristic appearance, there was absolutely no pyrexia either morning or evening, the highest point reached being 99.6° F. The pulse however, was rapid, being from 116 to 120 during the first three days. There was no albuminuria; desquamation began on the ninth day. He also mentions a second case, occurring in a child of about the same age, where, though all the distinctive signs of scarlatina were present, the only time there was any abnormal temperature was the evening of the second day; then it was 100.6° F. Here, too, there was marked rapidity of pulse, and he suggests that this is probably an important sign in diagnosing the rare cases of apyrexial scarlatina. His opinion is confirmed by Dr. Betz, who recently observed two apyrexial cases where the pulse was also very rapid.—*Münchener Medicinische Wochenschrift.*

Treatment of Tinea Tonsurans.—Dr. Simpson recommends the following treatment for ringworm of the scalp and body: Cut the hair short and wash the scalp well with tincture of green soap, and then apply the following solution with a camel's-hair brush:

℞. Hydrargyri chlorid. corrosiv ..... gr. j.
Collodii ..... ʒ j.
M.

This treatment may be recommended for three reasons: 1. The corrosive sublimate destroys the fungi. 2. The ether of the collodion penetrates to the root of the hair, conveying the corrosive sublimate to the seat of the disease. 3. The film formed by the collodion shuts off the supply of oxygen to the fungi, and thus helps to destroy them.

Cold Applications for the Relief of Palpitation.—Dr. Gingeot advises the use of cold applications for the relief of palpitation, more particularly of that due to nervousness. As to the method of applying cold, the simplest plan of all is to apply a wet sponge over the heart in the morning before dressing. At night, when in bed, the patient or an assistant may put a cold compress over the heart, well covered with dry bandages, to retain moisture and prevent any wetting of the clothing. When this compress is warm, the patient may remove it, and will probably fall asleep. There are objections to the ice-bag, one being the condensation of insensible perspiration upon the surface of the skin. The ether spray is a simple and convenient method of refrigeration. With proper instruction as to necessary precautions in the use of ether, the patient can apply cold in this way at any hour of the day or night. Palpitation of purely nervous origin seldom fails to be greatly benefited by the application of cold; and a certain success often follows its use in cases of palpitation due to organic disease.—*Revue générale de Clinique et de Thérapeutique.*

Faucial and Pharyngeal Tenesmus.—Mr. Lennox Browne proposes to apply the term "tenesmus" to the fauces and pharynx in those cases in which there is a continual inclination to void or to swallow an imaginary foreign body, accompanied by more or less cough, straining, and pain, either after or independent of functional exercise of the voice, with expectoration or welling up of small quantities of mucus, and occasionally, more especially in rising from sleep, by the discharge of small quantities of blood. Tenesmus would, in fact, not only apply to the condition now known as "globus hystericus," but would embrace all those numerous and various subjective symptoms which occur in the throat, and have not until recently been acknowledged to have other than a neurotic basis. The causes are mainly three: 1. Hypertrophy of the lymphoid tissue at the base of the tongue and the lingual tonsil. 2. Varix of the vessels in the same situation, the two constituting a condition called by him "throat piles;" and 3. A congestion, fulness, sometimes even obvious enlargement, of the thyroid gland. Functionally, the physical conditions causing throat tenesmus are mainly due to over-use, or wrong use of the voice, and to bolting the food; but the underlying constitutional causes are many, the principal one being a general varicose diathesis, shown by the occurrence of rectal piles, varicocele, varix of lower limbs, and cold feet. It is more frequent in women than men, and often appears at the menopause. In many cases there is concurrent relaxation of the uvula, removal of which fails to cure the patient unless the other conditions are recognized and concurrently treated. It is also seen in connection with, and, as was believed, as a result of, nasal stenosis. Treatment consists in destruction by electric cautery of the overgrown tissue and enlarged veins, with correction of the faults of health and of local function. Occasionally the hypertrophies are of sufficient size to enable them to be removed by a snare. Astringents or iodine fail to give permanent relief in any but the mildest cases.—*Journal of Laryngology and Rhinology.*

The Treatment of Cold Abscess.—Dr. Caird describes his method of treatment of cold abscesses as follows: The patient having been chloroformed and the skin shaved, and carefully purified with carbolic lotion (1 in 20), the abscess is opened by a small incision, into which the finger is at once passed. The whole of the wall which is accessible is now scraped bare with the finger-nail. It is easy to feel the pyogenic membrane peeling off in large flakes and shreds, and the finger readily recognizes where a perfectly raw surface is left. If the entire extent of the wall is not accessible, a second incision is made, the first opening is plugged, and from the second aperture the remainder of the cavity is now scraped well. It is advisable not to allow any pus to escape, since one can more easily strip off the lining membrane and judge of the thoroughness of the scraping when the abscess is distended. With the finger-nail the granulation tissue may be scraped away with impunity from off important structures, and the finger-pulp tells exactly how much is being done, and how much has to be done, in this respect differing widely from the sharp spoon, which cannot be used with the same freedom or accuracy. The pus is now allowed to escape, and the cavity is thoroughly washed out with boiled boracic lotion, warm, until the fluid streams away clear and transparent. Very short tubes may now be inserted, if need be, and a couple of sutures should be put in the wound, but not tightened up. The dressing consists of a large mass of moist gauze wrung out of carbolic lotion, and over that a large corrosive wool mass, secured in position by carefully applied bandages of Douret. Over all a piece of elastic webbing is carried, and the patient kept absolutely quiet in bed by means of suitable splints. On the following day the tubes may be removed, and the stitches tightened up. Future dressings are determined by the rules common to antiseptic surgery. Appended to the paper are the records of four cases, in which the method above described was put in practice.—*Edinburgh Medical Journal.*

Progressive Intestinal Atrophy.—At a recent meeting of the Society of Medicine of Berlin, Dr. Jürgens read a communication on a case of this kind. The patient had

suffered from general weakness, vomiting, and a painful sensation in the abdomen. There were marked motor disturbances in the legs, and the temperature remained constantly very low—usually under 97°, rarely 98.4° F. There was general anæmia and severe vomiting, so that intestinal obstruction was suspected, and rendered probable by an abdominal tumor being felt on palpation. At the necropsy the whole intestinal canal was of a dark reddish brown color, the upper part of the small gut greatly dilated, and the walls thickened by œdema. The brown coloration was most pronounced in the duodenum. The whole condition has been described under the name of hæmochromatosis universalis. Numerous diverticula were found in the small intestine. These result from impairment of the muscular coat, the wall giving way to the internal pressure, and sacculations forming which prevent onward movements of the contents and produce symptoms of ileus. This usually occurs in consequence of alcoholism; and in this case such a history was present. Degeneration of the muscular fibre of the gut, as well as of the cells of nerve-plexuses, is also observed. Nerve-endings frequently show fibrous transformation, almost always the result of degeneration of the sympathetic. Disturbances of the cardiac nutrition occur through paresis of the intestine. The liver is likewise brown, and has so much pigment as to suggest melanæmia. In discussing the case, Professor Leyden said that clinically it was one of progressive cachexia and weakness; the muscles were quite soft, and their electric irritability deviated much from the normal. This paralytic-like condition was ascribed to general cachexia.—*Berliner Klinische Wochenschrift.*

An Acetone-yielding Substance in Normal Urine.—Dr. Taniguti shows that a substance is present in normal urine which yields acetone when the urine is distilled with sulphuric acid. At least 10 parts of concentrated sulphuric acid should be added to 300 parts of urine, as on using less than this amount of sulphuric acid all the acetone does not come off on distillation. The whole distillate is made alkaline with sodium hydroxide and a solution of iodine in potassic iodide added. After twenty-four hours the precipitated iodoform is collected on a weighed filter, dried, and weighed. From the amount of iodoform thus obtained, the quantity of acetone is calculated.—*Zeitschrift für Physiologische Chemie.*

Santoninoxime as a Vermifuge.—Santoninoxime is obtained by heating five parts of santonin with four parts of chlorhydrate of hydroxylamine and from three to four parts of chalk, in the presence of alcohol. The product is eighty for each one hundred parts by weight of santonin employed. The substance consists of silky needle like crystals, white, insoluble in cold water, sparingly soluble in boiling water, soluble in alcohol and acetic acid. The crystals melt at 420° F., and rotate polarized light to the left. It has been praised as a vermifuge, and may be used instead of santonin. It can be administered in doses two or three times larger than the latter substance, without causing accident.—*Journal de Médecine de Paris.*

Stomach Washing in very Young Children.—In order to discover the therapeutic value of lavage of the stomach in very young children, Dr. Froitzky tabulated the results obtained in sixty five babies of from two weeks to four months of age. A Nélaton sound was used, with a glass funnel, and the stomach washed out with a three per cent. solution of salicylate of soda, in water which had previously been boiled. At least two washings were required to entirely stop vomiting. The treatment was well borne by the children. The author concludes as follows: 1. Lavage of the stomach is a valuable means of stopping the development of gastro-intestinal inflammation, especially if begun early. 2. The most favorable results are obtained in cases of dyspepsia without fever, especially if the stomach alone is at fault; the improvement is slower in gastro intestinal affections, and still less marked in purely intestinal trouble. 3. It is as useful in acute gastro-intestinal disease as in summer diarrhœa, but is not in itself sufficient, and must be aided by other therapeutic measures. 4. Chronic forms of gastro-intestinal disturbance are improved, but treatment must also be supplemented by other means.

Blue Milk.—Dr. Behr gives the results of a series of experiments on the bacillus of blue milk, in which the power of color production was lost. Observations have already been made in connection with the loss of color-producing power of the bacillus prodigiosus and bacillus pyocyaneus, and he refers to Dr. Heim's observation on the same question in connection with the bacillus of blue milk. He made his experiments with three sets of blue milk bacillus, and, although there was nothing peculiar about the plate cultivations, he found that one of them produced no color in sterilized milk, in neutralized agar, and in neutralized gelatine, even in very old cultivations. That it was the specific bacillus was proved by the fact that at a later period, in other cultivations, the characteristic color-reaction was obtained. In all cases it still retained its morphological peculiarities, it was actively motile, and flagella could be well demonstrated. Dr. Behr suggests that this is another proof that bacilli may for a time lose their specific characteristics; and although we are as yet unable to determine the exact conditions under which these characteristics are lost, such isolated facts enable us to hope that in time we may be able to modify the conditions under which different organisms exist, and that we may at will cause specific micro-organisms to lose their color, enzyme, and toxime-producing powers.—*Centralblatt für Bakteriologie.*

Cocoanut-Water as a Culture-Fluid.—Dr. George M. Sternberg, writing in the *Medical News*, of September 13, 1890, says that he has used the juice of the unripe cocoanut as a culture-fluid, and found it very satisfactory. The idea occurred to him during a visit to Cuba that this fluid might be a useful culture-medium for bacteria, and upon making the experiment I found that various species grew in it most luxuriantly. As it is contained in a germ-proof receptacle no sterilization of the fluid is required when it is transferred with proper precautions to sterilized test-tubes, or is drawn directly from the nut into the little flask with a long and slender neck, which I am in the habit of using for fluid-cultures. In these it may be preserved indefinitely, remaining perfectly transparent and ready for use. Heating the fluid causes a slight precipitate. In the investigations which I have made in Havana during the past two years I used this fluid very extensively and found it a great convenience to have a sterile culture fluid always at hand ready for use at a moment's notice. Moreover, it has certain special advantages for the study of the physiological characters of various bacteria and for the differentiation of species. It contains in solution about four per cent. of glucose, in addition to vegetable albumin and salts, which alone would make it a useful nutrient medium. Certain micro-organisms multiply in it without appropriating the glucose, while others split this up, producing an abundant evolution of carbonic acid, and giving to the fluid a very acid reaction. As obtained from the nut it has a slightly acid reaction, which makes it unsuitable as a culture-medium for certain pathogenic bacteria, but when desired it is a simple matter to neutralize it. For a large number of species of bacteria and for the saccharomycetes it constitutes a very favorable medium.

To Disguise the Taste of Quinine.—The following is recommended by the *Pharmaceutical Record* as an excellent menstruum in which to administer quinine in order to disguise its taste: Mass licorice, hot water, glycerine, each 20 parts. Dissolve and cool, then add alcohol 10 parts, and water 10 parts, or enough to make 80 parts in all. For each 3 grains of quinine sulphate in powder, or shaken with water, add 1 fluid drachm (or small teaspoonful) of the above preparation.

The Antagonism Between Iodine and Salicylates as Regards Exudations and Transudations.—From a study of this subject Drs. Rosenbach and Pohl have reached the following conclusions: 1. Salicyl compounds given internally pass not only into the urine, but into the fluids of serous cavities, also joints, peritoneum, and pleura. They appear in all transudations due to stasis, and also in purulent exudations, though in smaller quantities. But they are not to be found in the saliva, the intestinal contents, nor the bile. In particular, sodium salicylate cannot be found in the stomach, when, after its introduction into the rectum, it can be shown to be present in the urine. 2. Iodine preparations after internal or subcutaneous application pass into the urine and saliva; like the above, they are to be found in transudations into the skin, abdomen, and pleura in various diseases, but, unlike them, they never pass into serous or purulent exudations. Moreover, iodine, though freely given, is never to be found in the synovial fluids or membranes, whether in health or disease. 3. Sodium salicylate injected into joints or serous cavities, when transudations or serous or purulent exudations are present, is always to be found, after a short time, in the urine. 4. The same is true for iodine. 5. The fundamental difference, then, between iodine and salicyl is that the latter, however given, is found in all serous cavities and in the urine. Whereas iodine, given by the mouth in the usual doses, passes only into transudations, but never into joint cavities, whether normal or inflamed. The therapeutic consequences are self-evident.—*Berliner Klinische Wochenschrift.*

Psorospermosis.—At a recent meeting of the Medical Society of Christiania, Dr. Bœck showed a patient suffering from psorospermosis, which had existed for sixteen years. Papules, varying in size, were scattered, to a greater or lesser extent, over the whole of the body. This case was exactly similar to that shown at the Dermatological Congress at Paris by Darier, which he named *psorospermose folliculaire végétante.* In the sections which were exhibited, numerous encysted coccidia were observed situated in the epidermis, particularly in the stratum granulosum. The epidermis had become loosened from the papillary body, where the process was much developed. The papillæ were ramified and elongated. At a meeting held on November 20, 1889, two sons of the above-mentioned patient were shown by Dr. Bœck, both of whom suffered from this affection, which was situated on the same parts of the body as in the case of their father. Pyrogallic acid, used as an ointment, produced a favorable result. No applications had been used in the other case.—*Monatsschrift für Praktische Dermatologie.*

A Case of Tetanus of the Uterus Treated by Antipyrin.—Dr. Wright reports this case, treated in a lying-in hospital in Toronto. The patient was a primipara, aged twenty-two, of sedentary habits. Always been well, with the exception of leucorrhœal discharges for the last two years. The pelvic outlet was found to be slightly narrowed; pregnancy normal. First stage of labor prolonged, owing to rigidity of os and premature rupture of membranes. From these causes the duration of the first stage extended over twenty-four hours, although three fifteen grain doses of chloral hydrate were given to relax the os. The head then descended rapidly half down the vaginal canal, and progress again became slow. At the end of forty hours the head was well down in the perineum, but the rigidity of external parts rendered the pains ineffectual. Symptoms of exhaustion then began to appear. The pains became shorter and more frequent, while the pulse increased to over 100, and the patient complained of nausea and thirst. Before very long it became impossible to make out distinct intervals between the pains, and on examination the uterus was found retracted, and in a state of tonic contraction. Dr. Wright ordered three fifteen-grain doses of antipyrin, one every quarter of an hour. Before the second dose had been given patient felt easier. After the forty-five grains had been taken the pains were about three minutes apart, and the tetanic contractions had disappeared. The head, however, being very large in proportion to the outlet, was delivered with forceps under chloroform. The uterus took three-quarters of an hour to contract properly, after the administration of ergot in drachm doses. Dr. Wright remarks that the results obtained from antipyrin in this case would seem to justify its early use in uterine tetanus, before the muscle-fibres and nerve-centres are exhausted by prolonged tonic contractions. It seems probable that the drug acts directly on the nerve-cells in the parturient centre in the lumbar cord, lessening their irritability.—*Canadian Practitioner.*

Oxalemia.—Dr. Neidert records two cases, the symptoms of which he associates with existing oxaluria and, to use his designation, oxalemia. In both cases one of the parents was diabetic. The nervous symptoms were the most prominent. There occurred paroxysms attended with severe cardiac palpitation—especially at night, a distressing sense of oppression, and asthmatic seizures. Restlessness was marked. There was tremor, choreiform movements, and a staggering gait. Nervous dyspepsia made an additional complication. An attack of syncope was followed by increase of already excessive thirst, and by failure of appetite. Frequent examinations of the urine, which was passed in large amounts, failed to reveal the presence of sugar; but oxalate of lime was found in amounts out of all proportion to the amount and kind of food taken. There was loss of flesh and strength. Investigation permitted the exclusion of acute or chronic disease of the stomach. According to Neidert, in oxalemia there is an abnormal production of oxalic acid from the tissues of the body, owing to alterations in the central nervous system.—*Münchener Medicinische Wochenschrift.*

Microbes and Specifics.—Professor Rosenbach, of Breslau, discusses the question how specifics operate against micro-organisms which have harbored in the body and lighted up certain infectious diseases. They do so, not because they poison the bacteria, but because the medicament used robs the microbes of the power of reproduction, deteriorates their feeding-ground so much that they cease to multiply and form toxines, and thus lose their unlimited power of causing and maintaining destructive processes in the body to which they have gained admittance. Their reproductive power depends on an unlimited supply of nourishing material. They may remain living, and after a certain time—whether they have preserved their original form or passed into more permanent forms, such as spores, which can exist under most unfavorable outward conditions—they can be inoculated into new nourishing media, and reproduce themselves if the media, like artificial ones, have no active, living protective power; but for the animal and human body they have become temporarily innocuous, and will be, after longer or shorter time, eliminated by the regeneration of the tissues. If the medicament is too weak, or the number of the micro-organisms, in proportion to the regenerative powers of the body, too great, then a relapse occurs—an event which demonstrates most strikingly that the invaders were not slain, but only reduced to a state of sterility, of checked development, and that immediately after the extinction of the operation of the medicament used, they were ready to begin their reproductive process once more.—*Berliner Klinische Wochenschrift.*

The Extirpation of Carcinoma of the Rectum in Two Sittings.—According to Dr. L. Rehn, the sacral method of Kraske enables us to remove carcinoma of the rectum situated high up. Hemorrhage can be easily controlled and a normal sphincter can be retained. The advantages of the operation are well known, but the mortality is great, much more than the twenty per cent. now published would lead us to believe. The author lost three

of his first five patients. In two cases the circular suture was complicated by the formation of a fecal phlegmon. A third patient died in collapse twelve hours after operation. The first two cases were operated upon strictly after Kraske's method. Then the author in four cases made use of the osteoplastic resection by a preliminary operative procedure; incision on the left side of the sacrum and ilium, transverse division of the sacrum between third and fourth sacral openings; opening of the flap of the bone and soft parts to the right. His two last cases were operated in two sittings, and had a more favorable course. In his sixth case the patient contracted an empyema following an attack of influenza at a time when the artificial anus should have closed. The dangers of the operation are collapse and infection. The preliminary operation, as soon as we decide to transversely divide the sacrum, is of great moment for the patient. If the para-sacral incision is sufficient we should choose this as the most saving for the patient. It seems that some have overlooked the fact that Kraske, in his preliminary studies, established to his satisfaction that the parasacral incision gives in a remarkable manner room for operating. It remains Kraske's operation whether we operate simply by incision of soft parts or the resection of bone, partial or complete. The manner of operating is that the growth should be removed, not from below, but from behind and above. The chief danger is infection from fæces, the circular suture holds in the rarest cases only, the rectum bursts generally behind. As precautions against secondary infection we use, 1, iodoform gauze tampon (not always sufficient); 2, avoidance of the circular suture, the rectum is allowed to remain open in its posterior periphery and is split toward the anus; 3, colotomy after Schede; 4, Heinecke's measure. The author thinks that the above dangers may be avoided by two operations: preliminary operation, exposure of and loosening of the new-growth, thereby avoiding any wound of the gut. The central portion of the gut is made movable preliminary to subsequent suture; careful arrest of hemorrhage. The wound cavity is loosely tamponaded. The loosened gut is brought to the level of the external skin by passing strips of iodoform gauze underneath it. The patient receives opium for four days, then laxatives and injections are used. If it should now be shown that insufficient evacuation of fæces is caused by stricture, the intestine may be incised without danger above the stricture. About ten days after the first operation the gut is circularly closed, and after drains are put in the wound is closed. By this time the wound has become considerably smaller. A failure of the intestinal suture at this time will not be of any danger to the patient. In case the gut should tear while loosening the growth in the first step, then it is advisable to remove the growth at once; the central piece of gut is attached to the skin at the lower angle of the wound. The circular suture of the gut follows in a second operation.—*Annals of Surgery.*

Tubercular Endocarditis.—Dr. Tripier has observed a case of generalized miliary tuberculosis in which he found a tuberculous nodule on the under surface of the mitral valve, on the upper surface of which was an acute endocarditis. This endocarditis presented in places an exudate which was found to contain similar elements to the tuberculous nodule, thus establishing the similar nature of these products. This is supposed to be the first case in which a tubercular nodule has been found in the heart. It establishes the idea of the generalization of tuberculosis by way of the vascular system, an idea which has hitherto derived its chief support from the presence of tuberculous lesions along the veins and lymphatics, and the finding of bacilli within the circulatory apparatus. It also establishes the existence of acute tubercular endocarditis, which is known to be almost constantly present on the mitral valve in acute miliary tuberculosis. It is possible that this sort of acute inflammation may be the cause of the coexistence which has at times been noted of tuberculosis with an old cardiac lesion. These facts, however, will not suffice to overthrow the idea of an antagonism between heart disease and pulmonary tuberculosis. It would seem to be the case that, when there occurs a primary simultaneous localization of the disease in the heart and lungs, the lesions rapidly assume a greatly preponderating importance in one of the two organs. The pulmonary lesions then oppose themselves to the development of the cardiac affection or *vice versa.*—*Lyon Médical.*

Source and Significance of Albumin in the Urine.—From a number of observations on this subject, Dr. W. H. Porter (*The Post-Graduate*, January, 1891) has reached the following conclusions: First. That the albumin found in the urine, excepting that which occurs in the early stages of an acute exudative or diffuse nephritis, is a derived albumin and not serum-albumin. Second. In the early stage of an acute exudative or diffuse nephritis the albumin comes directly from the blood vessels, due to the inflammatory alteration in their walls, and is of the serum-albumin type. Third. That later in acute exudative or diffuse nephritis, when the vascular walls have partially recovered from the primary inflammatory damage, the albumin becomes more abundant in quantity, but now it is of the derived albumin type, and has been excreted by the damaged epithelial cells lining the uriniferous tubules. Fourth. That in all conditions, excepting the acute exudative or diffuse nephritis, where albumin is found in the urine, it is due to changes in the epithelium by which it is unable to do the work properly and excrete, or allows a derived form of albumin to pass through into the urine. Fifth. That the quantity of albumin contained in the urine is always in direct proportion to the amount of retrograde change in the epithelial cells. Sixth. That this retrograde change in the epithelial cells is secondary to an impaired nutritive condition at large, together with an overworked state of the renal cells, without a compensatory nutrition being sustained. Seventh. Viewed in this light, if we direct our treatment to improving the general nutrition of the system, and at the same time decrease the amount of work to be accomplished by the kidneys, we shall see many cases of complete recovery which must otherwise remain cases of albuminuria.

The Treatment of Whooping-cough by Cold Baths.—At a recent meeting of the Medical Society of Rouen, Dr. Bataille drew attention to serious forms of whooping cough, and their treatment with cold affusion, in those forms where the prognosis seems poor, either by reason of repeated vomiting, or from the complication with broncho pneumonia. The patients, from one to seven years of age, had previously been treated with antispasmodics and change of air. Three or four times a day, according to the severity of the case, the infants were placed naked in a tub, and a pailful of water at about 57° F. was poured over them. Three children, of the respective ages of one, six, and seven years, attacked with broncho-pneumonia in the course of whooping-cough, were thus treated, and after treatment from eight to sixteen days were cured. The affusion was not, however, rigorously followed up during the whole period, but was interrupted occasionally for twenty four or forty-eight hours, according to signs of amendment. These affusions have the advantage of not depressing, but produce a salutary stimulation of the respiratory muscles.—*L'Union Médicale.*

A Visible Heart.—The case is reported of a child, about a fortnight old, in whom the sternum and costal cartilages are imperfectly developed. The heart is seen most distinctly through the thin cutaneous wall of the chest. The shape and size of the auricles and ventricles, with the filling of the auricles with blood, are quite as visible for all practical purposes as if the organ were completely exposed to view.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, February 14, 1891.

THE SIGNS OF SANITY AND INSANITY.

AN editorial with this title appeared in the New York *Evening Sun*, January 17, 1891, relative to the recent decisions in regard to Dougherty and Stephani. Dougherty has been found guilty of murder in the second degree, and will be sent to the Criminal Insane Asylum at Auburn. Nothing is harder to define in clear and simple terms than insanity. Not less perplexing is the question of when an insane man becomes sane again. Churchill's definition is here as good as any. He says: "An insane person may be regarded as having recovered his sanity when a reference to the exciting cause produces no recurrence of his former delusions."

Next to insanity itself, the saddest thing in the world is the way in which the public regard it. The grossest ignorance still prevails concerning mental disease, for superstitions concerning the more complex and finer things are the last to be given up. While the idea of demoniac possession has in a measure departed, the notion of disgrace attendant on such possession still remains. To know what insanity really is might materially abate the public horror of it, and raise mental alienation to the social status of small-pox, typhoid fever, and measles. The late Dr. George M. Beard once read an important paper on "The Symptoms of Sanity and the Diagnosis of Insanity." This paper, he stated, had a twofold object: First, to show what a sane man is, in order to answer the question, "How can you tell a sane man when you see him?" The second object of the paper was to reconstruct the subject of insanity on the basis of evolution, to carry evolution into psychology, the law of evolution being the greatest generalization the human mind has ever reached. According to Dr. Beard the symptoms of sanity are as follows:

I. Activity of the instinct of self-preservation.
II. Adaptation to environment.
III. Correspondence of character to age and station.
IV. Rememberable consciousness.

Whoever responds to all these tests is sane, no matter how ill in body or mind. He who does not respond to these tests is an insane man, no matter how well he may be in body. It is possible for the mind to be impaired to a degree that is not necessarily serious, as in hysteria, hypochondria, neurasthenia, etc. But sufferers from these disorders usually retain activity of the instinct of self-preservation, adaptation to environment, correspondence of character to age and station, and rememberable consciousness.

Symptoms of mental disease begin from above downward, beginning with the tips of the branches and blossoms. The symptoms of insanity appear in the following order, the later acquisitions first disappearing and then the earlier:

I. There is a decline in manners, that is, minor morals; then more extensive moral decline.
II. Decline in the power of originating thought.
III. Decline in the power of acquiring thought.
IV. Decline in the memory of recent events.
V. Decline in the memory of old events.

Thus it will be perceived that there can be no insanity without moral decline. The law of proportion, which is the law of right conduct as well as of beauty, ceases to exist. Fact, as a point of view, gives way to mirage and dream. And between dreams and sane living there is a great gulf fixed.

Insanity has been defined as "a disorder in the power of adjustment of the organism to its environment." It is the manifestation in speech or conduct of disease or defect of brain. So called mental diseases are simply groups of symptoms. One of the symptoms of a diseased body is mental alienation. Whatever the real nature of mind may be, it is so intimately allied to organism as to be practically inseparable from it during life. The world confesses that it knows not the construction and nature of spirit. But physical facts abound, and a fair knowledge of inseparable mind and body—inseparable while life holds matter together—and of their unity of expression may be had for the earnest seeking. When the signs of sanity and of insanity are more a part of everyday education, manifestations in speech or conduct of disease, or defect of brain, will cease to be a disgrace. Then the insane will no longer be an outcast, but the recipient of best intelligence and tenderest care, like the weakling of a family upon whom is bestowed infinite attention, and to whom is given the choice of chances.

A NEW DEPARTURE FOR THE COLLEGE OF PHYSICIANS AND SURGEONS.

Now that it is an assured fact that the College of Physicians and Surgeons of this city has become a department of Columbia College, it must be acknowledged there is a mutual advantage in the arrangement which cannot be lightly considered. By means of it both institutions gain strength, one by the backing of a rich, strong, and progressive college, the other by the addition of a medical department second to none in the country. In so far as the latter can now be made independent of the number of students and their fees, will the cause of medical education be advanced and the standard of requirements be raised. Under the new rule the medical professors will receive regular salaries from the board of trustees of the college, but will reserve the privilege of nominating the members of their particular faculty. Not only is this understanding a perfectly proper one as guaranteeing the selection of duly qualified men by the trustees, but is a becoming concession for the addition of one million six hundred thousand dollars of real estate to Columbia. The President

of the Medical Faculty, Professor James W. McLane, who was chiefly instrumental in bringing about this desirable change of affairs, will be the Dean of the Medical Department and will represent it in the College Council. The College of Physicians and Surgeons, during nearly a century of existence, has kept itself well in the van of similar institutions here and abroad; has always shown a disposition to advance with the progress of events; has kept its scholarship high and its teaching abreast of the times. It is due to her to say this, even at the risk of making invidious comparisons with the sister schools here and elsewhere. With such a record behind her, and such a prospect before her, what may we not expect! All hail to the Medical Department of Columbia!

THE ART OF CYSTOSCOPY AND ITS USES.

The appearance of a text-book on cystoscopy by Nitze, of Dresden, is a reminder that surgery has made another advance into the viscera of man. It is now over ten years since cystoscopy was first attempted; but it is not much more than two years since its value was recognized. Now, if we may believe the statements of Nitze and of his reviewer, Dr. Willy Meyer (*Annals of Surgery*, June, 1890), the cystoscope is an indispensable part of surgical equipment, and is for the bladder what the laryngoscope is to the larynx.

The helps given by the cystoscope in diagnosis are enumerated by Dr. Meyer somewhat as follows: It shows absolutely whether the disease is in the bladder or not. One can learn to see out of which ureter purulent or bloody urine escapes. Hence we have here a means of solving the question which kidney is diseased, if there be but one affected.

More thorough knowledge of the forms of catarrh, a recognition of the presence of ulcerations, tuberculosis, and of foreign bodies, all follow from the use of the cystoscope.

But it is in the diagnosis of tumors of the bladder that most advance has been made and most help given.

Regarding this point Dr. Meyer gives the following word of advice and warning:

"As the accompanying catarrh of the bladder, which so terribly torments and weakens the patients, is in all cases carried into the bladder by the doctor with the sound or catheter, one should absolutely avoid the introduction of an instrument into the bladder of patients where a tumor is suspected. The cystoscope must be the first instrument in future which is resorted to in these cases."

The cystoscope has added some interesting facts regarding the physiology of urinary secretion. "Many," says our reviewer, "will certainly feel eager to observe once themselves how the urine, descending from the kidneys, enters the bladder with a rush at intervals of from thirty to sixty seconds—sometimes as long as five minutes—producing whirls in the water that had been injected into the bladder; how, at the same, time the mouth of the ureter first slowly contracts to the size of a very small groove and then again gradually enlarges to its former size, at this moment suddenly giving exit to the urine; how the mouth of the ureter remains in this middle position for a short while until the recurrence of the movement determines a repetition of the phenomena; how the displacement of the intra-abdominal organs during respiration reflects upon the vertex of the bladder (downward and upward rolling of the injected bubble of air); how the same spot of the wall of the bladder, especially on either side, shows rhythmic pulsation (transmission of the pulse of the external iliac artery)."

THE PATHOLOGICAL CHANGES RESULTING FROM INJECTIONS OF PARATALOID.

Virchow's observations upon this subject have already appeared. Dr. Browicz, of Korakow, has made similar studies and reached the following conclusions:

"1. That the changes occurring in tuberculous tissues after an injection of Koch's liquid are different from the necroses which usually accompany them. 2. That a specific form of inflammation is induced. 3. That this may assume a hemorrhagic form. 4. That, finally, the inflammation results in the destruction of the tuberculous tissue, and that this result is due to a distinct chemical action. Dr. Browicz considers that the tubercle bacilli may either be carried away by the exudation which is poured out, or else, if the disease is deeply seated, there is great danger of the organism being carried by the blood stream to healthy tissues, so setting up local or general tuberculosis."

Dr. Browicz's observations are very important in view of the fact that Koch thinks that his lymph produces only a coagulation necrosis and not an inflammatory or hemorrhagic process. His observations are confirmed in a measure by Professor Chiari, of Vienna, who gives the results of post-mortem examinations made by him in three cases of phthisis in which Koch's treatment had been employed. In all the tuberculous foci in the lungs there was great accumulation of leucocytes, with considerable fibrinous exudation round about. In the affected parts of the lungs, and in tuberculous ulcers in the intestine, there was marked hyperæmia, and in some instances signs of hemorrhage. There were large masses of tubercle bacilli in the bronchial tubes, and on the bases of the intestinal ulcers. In short, the appearances indicated abnormal exudative inflammation around the tuberculous foci, and (perhaps in connection with this process) a tendency to the expulsion of tubercle bacilli in the lungs and intestines.

Dr. Jürgens also reports the results of autopsies on two cases of advanced phthisis treated by Leyden with parataloid. In both cases the changes in the lungs were so wide-spread that only very small portions of those organs remained permeable to air. The tuberculous foci themselves presented no naked eye appearances which could be attributed to the specific action of the remedy; this, however, was due, according to Jürgens, to the fact that the greater part of the lung-tissue was destroyed by the disease. On the walls of the cavities he saw signs of hemorrhagic hyperæmia, but no trace of caseous substance. The pleurisy was of recent origin, and there was much sero-sanguinolent exudation. The tuberculous ulcers in the alimentary canal presented a remarkable appearance. In place of a grayish base, with red and swollen edges, they showed a surface covered with recent and very vascular granulations. The tuberculous ulcers in

the larynx also differed much from the ordinary type. In short, the tuberculous ulcers generally had lost their specific character, and had become transformed into simple ulcers. Where the ulcers had attacked cartilage, as for instance in the tracheal rings, a similar process had also been set up, the necrosed cartilage had come away, and the ulcer had healed. In the stomach, small and great intestine, and rectum, the tuberculous ulcers, though exhibiting numerous individual differences in detail, presented this common feature that in all of them the specific neoplasm had been eliminated and replaced by ulceration of benign character. In one of the patients who had tuberculosis of the kidney, that organ on section presented a caseous focus surrounded by a zone of intense hyperæmia. On microscopic examination granulation tissue was found, but no tubercle, no giant cell, only an infiltration of pus cells around the caseous centre.

Jürgens's observations, as may be seen, bear more favorably on the action of the lymph.

THE "MYSTIC" AND THE "FRANK."

THE *Saturday Review* has recently been discussing the subject of physicians in a philosophic manner, and it makes some points with regard to their characteristics which must be admitted to be essentially correct. It divides members of our esteemed profession into two classes: the "mystic" and the "frank."

The "mystic" physician, we are told, "is an undoubted survival of the savage medicine man, and his existence is only another proof that we have not yet quite emerged from barbarism. He is not at fault. He either believes in himself quite as firmly as the medicine man does, or he adopts the mystical plan deliberately, and because he knows that through it he is capable of doing more good than he could through frankness. He who should go to minister to a savage tribe would hardly think of treating its members as his intellectual equals. He would be much more apt to get them to take his medicine and follow his advice if he should mix in a few charms, spells, and magic incantations. It is precisely on these lines that the modern mystic physician moves, and it is precisely these accessories of sorcery or their modern substitutes which lend him their aid. If disease does not yield to his blandishments so much the worse for disease. Let it be anathema for existing when it ought not to exist. If the treatment be altered, there is no acknowledgment that a new theory of the ailment is to be tested; the patient is led to infer that the change of medicine is part of a plan formed within the deep recesses of the mystic's brain at the outset."

The type of the "mystic" thus described will be readily recognized. It pervades the cities rather more than the country. For if the rural population be less enlightened, it knows its medical men more intimately, weighs their character, and appreciates their motives.

The "frank" physician, says the *Review*, "may admit, to start with, that a physician is rarely certain in his diagnosis; that he must usually experiment a little at first. He tells his patient at the outset all he knows of the case, outlines the prospective treatment, with all its possibilities of change, and, in short, takes the patient into his confidence. His manner is free from grandeur, authority, or mysticism, and his language is colloquial and simple."

It is admitted that the above method of treatment will not do at all in the great majority of cases, and the "frank" physician has to adopt a trifle of mysticism at times and to vary his methods with the patient. Mr. Henry James, in "Washington Square," hits off this mixed type capitally when he describes a successful New York physician who explained his opinions to his patients but "always left an inscrutable prescription behind him."

The sympathies and aspiration of every honest physician impel him to frankness. And the more comprehensive his knowledge, the wider his experience, the more careful and conscientious his attentions, the less need he will feel for mysticism. The mysterious manner, the pedantic speech, and what may be called the heavy professional style, are indications of medical ignorance. Every decade there is a larger percentage of the laity who understand this and who are learning to appreciate the sincerity which goes with greater knowledge and a surer touch on the resources of the medical art. The positiveness that comes from knowledge is gradually taking the place of the mysteriousness and dogmatism that came from the dim appreciation of pathology as it was known in older times.

News of the Week.

An Opportunity for the Study of Contagious Diseases.—In accordance with a resolution passed at the last meeting of the Board, the Health Department has appropriated sufficient to pay an assistant physician to the Willard Parker Hospital a small salary. The term of service, as previously fixed, is six months. He must be a graduate in medicine, and preferably a hospital graduate. Applications to be made to Dr. D. M. Stimson, No. 11 West Seventeenth Street, New York.

New York Ophthalmological Society.—The following officers have been elected for the ensuing year: *President*, H. S. Oppenheimer, M.D.; *Vice-President*, J. B. Emerson, M.D.; *Secretary and Treasurer*, John E. Weeks, M.D.; *Committee on Admission*, J. S. Prout, M.D.; D. B. St. John Roosa, M.D.; Henry D. Noyes, M.D. Meetings are held monthly at members' residence.

The Cholera in Syria.—We have received from Dr. R. Condit Eddy, of New Rochelle, N.Y., a translation of an interesting Arabic letter from a native of Homs, Syria (the ancient Emessa), where the cholera has recently prevailed. The letter is dated Homs, January 3, 1891. "That you may know respecting the entrance of the disease into this city and its course here, I would state that it began here the sixteenth of October, 1890, and destroyed God's servants without mercy. But until the close of the month the people of the city did not apprehend danger from the spread of the disease among them, trusting to the excellence of their climate as a security against its violence. They concealed from the Government physicians the first cases, fearing the isolation of their dwellings by rigid quarantine regulations, and burying the dead in their gardens beside

their houses. The Government took all precautions by forbidding the sale of unripe or over-ripe fruit, and by closing the tanneries, whence issued injurious odors, and by burning sulphur in the streets. But by the close of the month of October the disease had made such progress that it could no longer be concealed, since there had occurred as many as two hundred cases, and the deaths amounted to one hundred and ten. It prevailed until the close of November, when God willed that this guest, who had stayed unwelcome and unhonored, should depart. The total of the deaths by cholera in the forty days was about two thousand—that is, there was an average of fifty deaths a day. The most of these deaths occurred among the poorer classes of the people, who paid little attention to cleanliness, and who were ill-fed and less able to resist disease. But many who were not poor died from their excessive precaution to escape danger; for they had heard that laudanum was a specific in this plague, and they therefore purchased opium of the druggists and dissolved it in arrack, and drank it without knowing the power of the drug, and without measuring the amount taken, and they died without the cholera touching them. Others died from the ignorance and bad treatment of quack doctors, but the most died from the poison of the cholera producing collapse, when the heart or the lungs refused to act, or when the kidneys did not perform their function." In the neighboring city of Hamah, about three thousand deaths occurred. It was estimated that about ninety per cent. of those attacked in the two cities died. After attacking Hamah and Homs, the cholera proceeded on its course southward and entered Tripoli, but remained there but a short time, and appeared with far less violence than in the cities it had previously visited, that is, of Aleppo and Antioch, besides those already mentioned. About eleven hundred cases were reported in Tripoli, and only three hundred deaths. The disease seems to have left Syria with the cold and rain of January. It remains to be seen if it will appear again there with the return of warm weather, as has been the case in past visitations of the cholera in the East.

The Woman's College of the New York Infirmary gives a reception to-day in celebration of the opening of its new building.

Low Birth-rate of Americans.—Some weeks ago we published an editorial based upon the statistics of the Eleventh Census, and showing an apparent deficiency in the birth-rate of Americans. This birth-rate in the decade 1880 to 1890 is apparently lower even than that of France. The *British Medical Journal* editorially copied the sentiments and the facts given by us under the head of "The Deficiency of Native-born Americans." The *Journal* is now getting credit for our observations. We are glad, however, that the subject is attracting attention, even though a British criticism had to be made first.

Dr. Frank P. Foster, the able editor of the *New York Medical Journal*, has been appointed Librarian of the New York Hospital Library. No better man could have been selected. We congratulate the library accordingly.

Koch's Remedy in Surgical Tuberculosis.—Dr. Eugen Hahn reports (*Deutsche Medical Wochenschrift*, January 1, 1891) 32 cases in which Koch's treatment was tried in the Friedrichshain Hospital at Berlin, from November 21st, up to December 23d. The injections given amounted in all to 300. Hahn found Koch's statements as to the action of the remedy confirmed. The cases treated embraced various forms of surgical tuberculosis, especially bone and joint disease, glandular affections, and lupus. The results were as follows: 16 were considerably, and 12 appreciably, benefited; in 4 no change was perceptible. In cases of tuberculous disease of the bones and joints the results were better when sinuses existed than in others in which there was neither sinus nor surgical opening. In one case, in which the knee-joint was resected, reaction, which had been very powerful before the operation, entirely ceased.

The Causes of Mammary Cancer.—From a careful study of statistics, Dr. H. Schulthess concludes that puerperal mastitis, trauma, and perhaps eczema, are the only etiological factors which can be regarded as of decided importance; menstrual troubles, gravidity, sexual intercourse, lactation, and heredity have no causative influence.

Government and the "Parataloid."—Although the Prussian Government has definitely abandoned the monopoly of the production of Kochine, measures are being prepared for a rigid state control of its sale and a strict supervision of its manufacture. Chemists will not be allowed to sell the lymph unless the state analysts have confirmed its purity. Under an order from Minister von Gossler, all clinics of pathological institutes of the Prussian universities report the results of treatment by the Koch method. So far as received, a majority of the reports are in favor of the treatment. The statement of Professor Hennoch, the great authority of the Berlin University on children's diseases, regarding the danger of treating children with the lymph, is supported by other authorities.

Hygiene of our Public Schools.—The primary schools are those which the State should support most generously and look after most watchfully. Yet in this city they are the worst of all the grades. Dr. H. D. Chapin has been investigating some of the city primary schools, and he finds that the smallest quantity of air-space allowed by law in tenement-houses is four times as great as the largest required by law in the public schools. In the three lower classes the allowance is as 7 to 40, or as 1 to 5.7. The provision for changing even this small quantity of air is inadequate, while in some schools the air is made still more noisome by the gas which it is necessary to burn in order to see. In addition to this, the primary school teachers are the poorest paid and have the largest classes.

Syphilitic Anæmia.—Dr. J. V. Hjelmman, reports in the *Finska Lakaresallskapets Handlingar*, for August, 1890, the results of a number of examinations of the blood in syphilitic patients, made to determine the nature of the anæmia accompanying the disease. The following are his conclusions: 1. The anæmia observed in recent cases of syphilis attains its maximum during the period of eruption. 2. In proportion as the general symptoms disappear the blood regains it normal composition. 3. Mercury administered in ordinary doses plays no role whatever in the production of this anæmia.

Examinations for Army Medical Appointments.—An Army Medical Board will be in session in New York City, N. Y., during April, 1891, for the examination of candidates for appointment in the Medical Corps of the United States Army, to fill existing vacancies. Persons desiring to present themselves for examination by the Board will make application to the Secretary of War, before April 1, 1891, for the necessary invitation, stating the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from whence they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates, based on personal knowledge, from at least two physicians of repute, as to professional standing, character, and moral habits. The candidate must be between twenty-one and twenty-eight years of age, and a graduate from a regular medical college, as evidence of which his diploma must be submitted to the board. Further information regarding the examinations may be obtained by addressing the Surgeon-General United States Army, Washington, D. C.—C. SUTHERLAND, Surgeon-General United States Army.

The Warren Triennial Prize.—This prize was founded by the late Dr. J. Mason Warren in memory of his father, and his will provides that the accumulated interest of the fund shall be awarded every three years to the best dissertation, considered worthy of a premium, on some subject in physiology, surgery, or pathological anatomy; the arbitrators being the physicians and surgeons of the Massachusetts General Hospital. The subject for competition for the year 1892 is on some special subject in physiology, surgery, or pathology. Dissertations must be legibly written, and must be suitably bound so as to be easily handled. The name of the writer must be enclosed in a sealed envelope, on which must be written a motto corresponding with one on the accompanying dissertation. Any clew given by the dissertation, or any action on the part of the writer which reveals his name before the award of the prize, will disqualify him from receiving the same. The amount of the prize for the year 1892 will be $500. In case no dissertation is considered sufficiently meritorious, no award will be made. A high value will be placed on original work.—J. W. PRATT, Resident Physician, Massachusetts General Hospital, Boston, Mass.

Dr. C. C. Lancaster, of Knoxville, Tenn., died on February 3d, of blood-poisoning from a wound contracted while operating. Dr. Lancaster was a graduate of Richmond Medical College, and Professor of Materia Medica in the Tennessee Medical College.

The Charities of the State.—The State of New York expended over sixteen millions last year in caring for paupers, insane, and the defective classes. The State had 16,022 insane in custody, last year it maintained two educational institutions for the blind, and seven for deaf-mutes. The poor-houses last year sheltered 22,000, while 97,018 received out-door relief. The State Board of Charities in making its annual reports gives the above figures, and urges the importance of its being allowed to continue its supervision of insane asylums.

The Human Curiosities of a Great City.—New York may never get rapid transit, a World's Fair, or a straight census, but it is advertised to have a lady from Missouri, eight feet high; a fat woman, weighing nine hundred and nineteen pounds; and a two-headed giant, eleven feet tall. There is always something here to stimulate local pride and minister to the joy of living.

A Battle between Doctors.—Although the matter has been to a great extent kept secret, says *The London World*, a battle between homœopathy and allopathy, has raged over the sick-bed of Princess Henrietta of Flanders, precisely similar to that which occurred at the commencement of Lord Beaconsfield's fatal illness. Her mother, who is an ardent homœopathist, called in Dr. Martiny, the head of that school of medicine, and all the eminent orthodox physicians declined to meet him in consultation. The attitude they assumed necessitated the summoning of a provincial practitioner by telegraph, and has given an opportunity to a young military doctor, who considers obedience the first duty of his calling.

Does Man Menstruate?—Paul Albrecht, in *L'Anomale*, calls attention to the fact that white blood-corpuscles appear in the urine of men at regular intervals, are present three or four days, and then disappear. This, he claims, is a kind of menstruation. Men with excessive hypospadias menstruate. He claims this is a proof of the independence of menstruation and ovulation.

A Deciduous Man.—At a recent meeting of the Chicago Medical Society Dr. J. Frank reported a case where a man every July shed his skin. He was taken with feverish tremors, increasing almost to paroxysms. He undressed, lay down, and within a few minutes the skin of the chest began to turn red. The redness rapidly extended over the entire skin, and the feverish tremors continued uninterrupted for about twelve hours. Then he arose, dressed, and walked about in perfect health. The skin now commenced to peel, and ten hours later it began to come off in great patches. From the arms and legs it could be pulled off exactly like gloves or stockings. As the old skin came away a new epidermis, as soft and pink as a baby's, was revealed. This new skin was very sensitive; the patient had to wear softened gloves and moccasins for about a week. After the old cuticle had been entirely removed, the finger and toe nails began to drop off—new nails literally crowding them out. Finally the change was complete—the man had a new skin and a new outfit of nails, and was ready to return to the mines. The shedding began in his first year and recurred every July thereafter.

Deaths of Eminent European Physicians.—Dr. George Gulliver, Physician to the London Fever Hospital, and Assistant-Physician to St. Thomas's Hospital, died on January 17th, aged forty years.

Surgeon-General T. G. Balfour, M.D., F.R.C.P., F.R.S., died recently, aged seventy-eight years.

Dr. Jules G. F. Baillarger, formerly President of the Paris Academy of Medicine and one of the leading alienists of France, died on December 31, 1890.

Dr. Giambatista Borelli, one of the leading Italian surgeons and a Senator of the Kingdom, died on January 10th, aged seventy-eight years.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, December 5, 1890.

ANDREW H. SMITH, M.D., PRESIDENT PRO TEM.

Perineorrhaphy; Its Indications and Methods, with the Description of a New Form of Suture.—DR. CLEMENT CLEVELAND read the paper (see p. 193).

DR. H. C. COE, an invited guest, said he had seen Dr. Cleveland perform this operation, and he had been very much pleased with it. The question had arisen in his mind whether it would be well adapted to those inside tears lying principally in the pelvic floor. But the reader had already explained that in those cases he would employ some additional inside sutures.

Regarding the pathological anatomy of ruptures of the perineum, he thought there were still a good many facts not yet made entirely clear, especially in cases of deeper lesions unaccompanied by much tear outside. Whether the state should be called one of subinvolution, or of overstretching of the tissues, or of actual giving way of the pelvic fascia and muscles, had not been made clear to his mind by dissections. That there was some serious lesion would appear from rolling out of the anterior and posterior walls of the vagina, demanding an operation, although in some just such cases there was no apparent lesion of the pelvic floor.

A Quick Operation.—The advantage of Dr. Cleveland's method of operating seemed to be in the rapidity with which it could be done, and also in the fact that it brought the parts closely together. He would think it especially adapted for the immediate operation. But the whole subject of perineorrhaphy, although an old one, was yet one on which a good deal of study might well be devoted, especially as to the intimate lesion present.

Like other operators, he had seen some cases of extensive injury of the pelvic body unaccompanied by serious symptoms so long as the supports of the uterus retained their tone and the vaginal walls remained in contact with each other. In fact, the object of the operation of perineorrhaphy was to bring the anterior and posterior walls into apposition. Whether Emmet's operation accomplished repair of the deeper tears or not, speaking from an anatomical stand-point, was not certain, but it certainly did to all intents and purposes restore the vagina to the condition it was in before the injury.

DR. GEORGE M. TUTTLE, an invited guest, said his attention had been called by Dr. Cleveland to this operation some time ago, and he had availed himself of the opportunity of performing it in two cases. There was one statement in the paper to which he must take exception, as Dr. Coe had done. It was that all tears of the perineal body were of significance. He thought tears into the body of the perineum had often been seen which had given no subsequent trouble. He had been particularly impressed with the importance of tears which resulted in loss of power in the levator ani muscles. That, it seemed to him, had been the significant feature of most tears in the lower pelvic floor. He thought it was still a question as to just what anatomical structures were involved, whether the fibres were torn, or only overstretched. But when they were impaired he thought one seldom failed to see symptoms.

To further illustrate his meaning, he referred to a case seen a few months ago, that of a woman whose posterior vaginal wall, perineal body, and the wall of the rectum were torn fourteen years ago. The tear extended an inch and a quarter up into the rectum. Yet there was absolutely no want of apposition of the vaginal walls, no prolapsus of the uterus, no symptoms whatever referred to the tear as a tear of the perineal body. The tone, the power of the muscular structures seemed unimpaired to the touch of the hand placed upon them, excepting, however, the sphincter ani. There was no rolling out of the vaginal wall, but there was entire lack of control over the bowel when the passages were soft The case showed that where the sphincter ani was not involved a tear through the perineal structures might not produce symptoms.

Regarding the operation described in the paper, it had impressed him by the neatness and despatch with which it could be performed. His first operation took about six minutes, the second about the same time. But it did not seem to him to fully meet the indications of the Emmet operation, the object of which was to restore to position the relaxed pelvic floor by pulling up on the sulci at either side. But by introducing sutures at the upper angle in the manner he had described it would seem Dr. Cleveland had met that objection. With the exception of the technique in the passing of the sutures the operation seemed to bear a close resemblance to previous operations which had in view bringing the opposite walls of the vagina together. It seemed to meet the requirements of close apposition without leaving pockets. It did not make the repaired structures so strong at the sides as did Emmet's operation. He believed it would prove extremely valuable in operations for immediate repair after labor.

DR. CLEVELAND feared he had not made himself very clear with regard to the necessity of the operation in all cases. When he said positively the operation should be done in all cases, he had in mind recent cases. In other words, the immediate operation should be done in all cases of perineal injury. It did not follow, however, that all cases not operated upon immediately would have symptoms demanding the secondary operation. The object of the immediate operation was to avoid danger of symptoms developing in the future. He did not think there was any operation, Emmet's included, which would entirely restore all the structures which might be torn during labor, but Emmet's came as near to it as any.

Ingravescent Apoplexy.—DR. C. L. DANA introduced a case of this kind by remarking that, some months ago, he had presented specimens to the Society, in two cases, illustrating a form of apoplexy which had been described by Broadbent under the name ingravescent or progressive apoplexy, a form which he thought deserved to be ranked as a special type. Dr. Dana had recently had another case of this kind in a woman, thirty-eight years of age, a native of this country, married, rather fleshy. He was able to obtain very little of the antecedent history further than that during the past two or three years she had had attacks of epilepsy, the fits coming on apparently at each monthly period, and at no other time. On the morning of November 19th she had a fit, this being her menstrual period, and fell on the floor striking the head. She lay unconscious, and was taken in that condition, a few hours afterward, to the hospital. In the hospital she lay in bed profoundly comatose, with abolition of all the reflexes, the pupils immobile, the breathing rather stertorous, the face somewhat flushed—in short, with the symptom of profound cerebral pressure. She lay in this state without special change until death, thirty hours after the onset of the attack.

As was his custom in such cases, he had the temperature taken in both axilla and rectum every few hours. The temperature (Fahrenheit) was first taken at 5 P.M., about eighteen hours after the first shock. 5 P.M.: Right axilla, 102.4°; left, 102.2°; rectum, 104.4°. 9 P.M.: Right axilla, 101.7°; left, 102.6°; rectum, 103.9°. 1 A.M.: Right axilla, 102.4°; left, 103°; rectum, 105.2°. Death at 3 P.M.

It was seen that while the temperature in the axilla was about 102°, in the rectum it reached about 105° F., or a difference of three degrees in the two localities. It was to be remarked, also, that while the patient was evidently

in profound hemorrhagic trouble, yet there was no depression of the temperature, at least not when the record began, twenty hours after the first attack.

At the autopsy they found an extensive hemorrhage, involving the second and third parts of the fourth temporosphenoidal convolution on the left side, breaking externally and also internally into the ventricles. It was evidently from one of the posterior branches of one of the capsular arteries, the same artery which broke in the progressive hemorrhage described by Broadbent. Usually, however, the hemorrhage was not so great as in this case. It cleft its way in between the layers of white matter, and for one, two, or three days might not break either externally or into the ventricles, in which case there were not at first such severe symptoms. Their severity, however, gradually grew, until finally the blood broke into the ventricles when all the symptoms of ventricular hemorrhage appeared. This case, he thought, was of interest in showing that the same artery might break and yet not produce the typical symptoms of ingravescent apoplexy. The case had also interested him in relation to the temperature. He thought this should be carefully studied in all cases of apoplexy.

Gall-stones Frequent; Hepatic Colic Rare.—Dr. H. M. Biggs inquired of Dr. Kinnicutt whether a gall-stone could enter the cystic duct and afterward return to the gall-bladder and there be no return of the attacks of colic. He had been impressed in autopsy work by the frequency of large numbers of gall-stones, especially in elderly people, there having been no history in many instances of hepatic colic. He had sometimes found in a single day among autopsies on Blackwell's Island two or three cases in which the gall-bladder was completely filled with stones, in some instances with very large stones, yet the subjects, who had been inmates of the institution for long periods, had given no history of hepatic colic.

Dr. Kinnicutt had been impressed by the same fact. The special point which he had wished to make in connection with his own case was, whether, when there was a history of attacks of biliary colic without the occurrence of jaundice to indicate that the stone had passed beyond the usual limit in the duct, and without the appearance of stones in the stools—whether in such a case it would not be advisable to entertain an operation. He believed that, sooner or later, when there was a large stone in the gall-bladder, death would result. With the presence of a very large stone the history was common enough that it found its way by ulceration into the intestinal tract, and when so large as the stone presented, would necessarily result in intestinal obstruction.

Dr. Biggs remarked that another feature had impressed him at autopsies on old people, namely, that not infrequently the gall-bladder was found almost or quite obliterated, having contracted down on a collection of gall-stones, and atrophied or ulcerated.

Dr. Andrew H. Smith asked whether any limit could be fixed as to the size of a stone which would refuse to pass through the intestine after having been proved to be too large to pass through the cystic duct. In his opinion there was considerable margin.

Dr. Kinnicutt thought it difficult to say how large the stone would have to be in order to cause intestinal obstruction after having refused to pass through the cystic duct. At any rate, he had always felt that if he had hepatic colic due to a stone too large to pass the cystic duct, he would desire an operation, and one reason for desiring it would be the fear that the stone, if it reached the intestine, might not pass safely out.

Dr. A. H. Smith, having elicited the information that operations for removal of stones from the cystic duct had not proven very successful in this city, said he thought danger of peritonitis might be avoided by first making an incision and causing adhesion to take place between the liver and abdominal walls, and after a few days proceeding to remove the stone.

Is Jaundice always Absent?—Dr. Kinnicutt said it was claimed by Mr. Tait that in cases of gall-stones jaundice was absent, for a stone which would pass through the cystic duct would not be so large as to obstruct the common duct and thus produce this symptom. Yet Dr. Kinnicutt had seen at least three cases in which the diagnosis was made of gall-stone, and in which the gall-stone was found, and there had been persistent jaundice covering a period of several months. Mr. Tait seemed not to have taken one fact into consideration, namely, that while the common duct was larger than the cystic, yet where the former merged with the duodenum it was as small as any portion of the cystic duct. Thus one could readily understand how a stone, after passing through the cystic duct, might become lodged in the lower portion of the common duct. He had seen one such case, in which it was very difficult to extract the stone, which had become impacted in the duodenal extremity of the common duct.

Dr. Biggs remarked, as bearing on the question of jaundice, that he had seen several cases in which gall-stones had lodged in the gall-duct in the liver, being in one half a dozen in number. In such cases there must necessarily be obstruction.

Dr. Kinnicutt asked whether in those cases there had been attacks of biliary colic; if not, they would have no bearing on the question raised by Mr. Tait.

Dr. Biggs replied that he did not know.

Rupture of the Kidney.—Dr. Andrew H. Smith narrated a singular case which had very recently come under his observation in the Presbyterian Hospital. The man entered on Tuesday, giving a history of having been perfectly well up to Sunday, excepting a little constipation. On Sunday afternoon, without known cause, he was seized with pain in the right iliac fossa. The pain grew more and more severe until Tuesday, when he was admitted to the hospital. His temperature was then 102°–102.5° F., there was plainly visible tumefaction in the right iliac fossa, McBurney's point was very well marked (the puncture-point midway between the umbilicus and the superior spine of the ilium), there was some tendency toward general tumefaction of the abdomen. The patient's face showed a very anxious expression, and he was passed over to the surgical side for operation for appendicitis. But some delay took place before the operation could be done, and then it was observed that the tumefaction and sense of resistance had extended posteriorly, and, in fact, were more noticeable in the lumbar region than anteriorly. At about that time blood appeared in the urine. This fact led to an exploratory puncture over the kidney. Bloody urine was withdrawn. An incision was then made in the usual situation for reaching the kidney, and a large sac was opened, containing clots of blood, fluid blood, and urine. On further examination the kidney was found to be ruptured a distance of three-fourths of an inch or more in length. There was nothing to explain the accident. The patient was doing well. There were no signs of peritonitis. The tumefaction would seem to have been due to distention of the intestine. It was only on account of the delay, during which the physical signs changed, that an operation was not done for appendicitis.

Besides the singular points in the case already mentioned, others were the absence of traumatism and of blood from the urine when the patient first entered the hospital. There was no account of hæmaturia before his admittance. In rupture of the kidney, of which there was no history until the operation, one would expect extravasation of blood into the pelvis of the organ. If it was possible for the blood to be at first cut off from the urinary passages, how could one account for its gaining access thereto subsequently? The rupture in this case was rather on the convex surface of the organ.

Dr. Tuttle asked whether the blood had found its way under the peritoneum and produced the tumefaction which had existed in the iliac fossa.

Dr. Smith replied that, as well as he could judge while

looking on during the operation, the blood extravasation had not extended around in that region.

Dr. Kinnicutt had seen a tumor from hydronephrosis push the intestine before it and produce an enlargement in the iliac fossa. The intestine lying over the very large mass caused tympanitic percussion sound and thus obscured the diagnosis.

Dr. Cleveland said he had reported a case of pyonephrosis to the society about a year ago in which the tumor gave the impression of being connected with the ovary, and a positive diagnosis could not be made until the abdomen had been opened.

Hæmaturia with Brief Cerebral Symptoms.—Dr. Andrew H. Smith said he had seen another singular case about a week ago, that of a man about eighty years of age, who had during the past four or five years had recurrent attacks of hæmaturia, unaccompanied by pain or other condition to explain its origin. Last week he was passing urine which contained a good deal of blood, without any pain, without rise of temperature, when suddenly the urine stopped after a small quantity had passed. The little which had passed was composed almost entirely of blood. In a very few hours the patient became comatose and apparently moribund. This was about one o'clock in the afternoon, and Dr. Smith was called in the evening. When he arrived the urine had resumed its flow, the cerebral symptoms had entirely disappeared, and the old gentleman was as lively and happy as usual. Dr. Smith said he could only suppose that the blood had extravasated from the kidney, that a clot had formed, occluding the ureter, that the other kidney through reflex action had ceased its function, or, possibly, there had been but one kidney, and that even during that brief time the symptoms of so-called uræmia developed. When the clot finally pushed its way down, the kidneys again began to act and the mental condition cleared up at once.

Dr. Kinnicutt thought it strange that uræmia should have developed so suddenly unless there were antecedent kidney trouble.

Dr. Smith thought it likely there was a contracted kidney, but he had seen the patient only once, and the family physician had given no further account of the case than what he had stated.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS.

Stated Meeting, January 22, 1891.

Egbert H. Grandin, M.D., Chairman.

Election of Officers. — Dr. Grandin was re-elected chairman, and Dr. I. H. Hance was re-elected secretary for the ensuing year. In thanking the members for the honor done him in re-electing him chairman, Dr. Grandin gave a special invitation to general practitioners to be present and take part in the proceedings of the section.

Specimen of Ruptured Tubal Pregnancy.—Dr. H. J. Boldt presented a specimen, consisting of the ruptured tube with placenta, also the ovary, removed from a woman who had last menstruated in November. Later she had hemorrhages and pain in the left ovarian region. The uterus was found somewhat enlarged, retroverted, and to its left was a mass about half the size of a man's fist. He suspected ectopic pregnancy and advised an operation. Previous to operating this morning, the mass could no longer be felt, the woman had been taken with cramp-like pains, and was pretty well exsanguinated. The probability was that rupture had taken place, and this was proven to be so after opening the abdomen. There was over a quart of free blood in the cavity; the left tube had ruptured, and contained a placenta. He did not feel justified in searching for the fœtus, which must have been insignificant in size.

Papilloma of the Ovary Developing soon after Laparotomy.—Dr. Andrew F. Currier related the case of an unmarried woman, aged twenty-six, who had suffered a long time from dysmenorrhœa. On opening the abdomen, he found in addition to a small uterus which was fixed in the pelvis, a small cyst of the left ovary, containing one or two drachms of fluid. He evacuated the cyst and excised the diseased tissue as far as he could discover that it was diseased, and closed the wound. He also shortened the round ligaments internally after Wylie's method. Except for a small abscess in the abdominal wound, the patient made an uneventful recovery, and went about very well for about a month, when, without any evidence of acute illness she began to droop physically, and after another month she was brought back to him, when he found that the uterus, which had been fixed anteriorly, had become detached on one side.

He suggested that the operation be done over. On opening the abdomen the pelvis was found solid with adhesions, although two months had elapsed since the first operation, and there had been no history of acute peritonitis. On lifting the left ovary, the one previously operated upon, he found a tumor as large as a man's fist, which proved to be a papilloma. A cyst of considerable size had also formed in the other ovary. It was new in his experience for a semi-malignant disease to develop in so short a time after an operation of the character described. He asked the members for information, but none responded.

Under what Conditions can Electricity be of Positive Service to the Gynecologist?—Dr. Currier read the paper. He said that to those who were familiar with electricity it might seem extremely elementary. For the general practitioner, however, this might prove a virtue, for according to his experience, most works were too abstruse and confusing. He thought there was much prejudice against this therapeutic agent on the part of some, and too much laudation of its usefulness on the part of enthusiastic supporters. The instruments and machinery, he said, were costly, and their proper application in medicine meant more than play. Success could not be obtained by mere dabbling.

The author divided his subject into, 1, apparatus; 2, indications and contra-indications; 3, cautions and objections. So far as concerned the faradic battery, the simpler and more portable the better. The fundamental principle underlying this form of electricity was that it stimulated the muscular fibre. He did not go into the virtues of long and fine and short and thick wires. Regarding the galvanic current, the positive pole attracted the acids, and acted like astringents and hæmostatics; the negative increased the vascularity, and was sedative, but pain might be relieved by either current. He found the Law or Léclanché cell answer every purpose. A rheostat and milliampère meter were indispensable. He used cords connecting the battery with the electrodes nine feet in length, different colors for the two different poles, and preferred Martin's abdominal electrode to that made of clay, although many had discarded it on account of the cost of platinum. He had had some tips made of Bessemer oxidized steel for use on the intra uterine electrode. With a battery and outfit costing in the neighborhood of two hundred dollars one could get a current of over two hundred and fifty milliampères.

Remembering the difference in action of the two currents, one would never make a mistake and use the negative pole to stop hemorrhage. The author admitted that not until some months past had he given sufficient attention to treatment by electricity to be able to use it with any great amount of satisfaction. The number of cases (twenty-three) which he had to report was not sufficiently great to justify positive conclusions. They included some of pain following removal of the appendages, etc., hemorrhage, inflammatory exudate, subinvolution, fibroids, etc. As to uterine hemorrhage, he knew of nothing which would more successfully check it than the positive pole of the galvanic battery. The hemorrhage in one of his cases arose from an interstitial myoma, in another

from a malignant growth. In three of four cases of inflammatory exudate following peritonitis, the exudate disappeared under electric treatment. In sterility, no one method could be considered infallible. He had used the faradic current with success in two cases out of five in which the fault seemed to be want of development.

For supersecretion in the uterus or vagina the positive pole was far more valuable than astringents, and curretting was not always practicable. The same agent used to check the glandular discharge could also be employed on the erosions on the os. In three cases thus treated the result had been satisfactory. It was not strange that the electrical outfit should appeal to the hysterical woman's imagination. Whether it produced a beneficial effect in any other way he did not know. Uterine subinvolution might mean discomfort, hemorrhage, sterility, etc. The Faradic current, which stimulated muscular contraction, would seem to be indicated. He had obtained good effects from electrical treatment in a number of cases of uterine subnutrition, characterized by amenorrhœa or dysmenorrhœa, sterility, etc.

In the line of contraindications, he said that on several occasions patients felt faintness and dizziness under the treatment, and the current was then at once cut off. In one case of exophthalmic goitre with rapid action of the heart, the use of the positive pole to stop hemorrhage arising from a uterine myoma was attended on two occasions with signs of commencing collapse, and he declined to experiment further. The case taught him the importance of always examining the heart first, and in his opinion an irritable heart should be a contraindication. He thought he had seen evidences of shock due to rapid reversals of the current, although some claimed therapeutic advantages for this procedure. A number of precautions and objections could be offered in electro-puncture.

The Treatment of Menorrhagia and Metrorrhagia by the Chemico-galvano-caustic Action of the Positive Pole.—Dr. A. H. Goelet, the author, being absent, Dr. Hance read the paper. In this method of treating the conditions named, one must take into consideration the state of the surrounding tissues. If there were periuterine inflammation it was necessary to proceed cautiously, feeling one's way to the use of higher currents which were sometimes necessary to control bleeding. Never use more than thirty milliampères at the commencement. Where hemorrhage was apparently aggravated instead of checked, it was probably due to some fault on the part of the operator or movement of the patient. Slight anæsthetic effect of chloroform inhalation might be necessary in sensitive patients. To produce permanent effect in controlling uterine hemorrhage, a decided caustic action from the positive pole was called for. There were two methods, one consisting in applying the platinum electrode to the whole canal at once, and the other in treating it by sections, though at the same sitting. The cervix should be avoided. It might be necessary to dilate. Under the first method, the electrode touching the whole cavity of the uterus, 50 to 100 milliampères usually proved sufficient, sometimes 150 were called for. Under sectional treatment 100 to 150 milliampères were reached at the first sitting if possible; it might be pushed still further if required. It might not be necessary to repeat it for a week if antiseptic precautions were employed. Where there was fungous endometritis the result would be more prompt after thorough curetting. Where the hemorrhage followed an abortion the curette should always be used, and positive cauterization afterward if hemorrhage persisted. In hemorrhage from uterine cancer and destruction of tissue, the galvano-cautery wire produced more prompt effects than chemico-galvanic cauterization.

The author cited two cases in which the positive galvanic treatment stopped the hemorrhage after the curette in other hands had failed; also one in which it was successful against hemorrhage due to a fibroid. Having arrested the hemorrhage in the latter, he went on to treat the fibroid with negative electricity, running the current up as high as one hundred and fifty milliampères five minutes at a time. The tumor greatly diminished.

Dr. Massey, of Philadelphia, was requested to open the discussion. He liked the tone of moderation shown in Dr. Currier's paper. He would advise never to give intrauterine electrical treatment if vaginal would answer, and to use as small doses as would accomplish the purpose. Yet in fibroid tumors, after attempting small doses, he was sure we must use large ones. If large vaginal doses did not answer in chronic metritis, use small intrauterine if there were no contraindications, such as tubal and ovarian disease. He treated exophthalmic goitre with five to eight milliampères provided no shock resulted. He was becoming more favorable to electro-puncture for fibroids, having thus far seen no bad results. He attributed this to the use of an insulated needle, only a quarter of an inch, which projected into the tumor, being exposed. Two hundred milliampères could thus be passed, and not influence the punctured mucous membrane. He preferred to puncture through the vagina, not through the uterus. Without puncture, he had seen tumors go down more rapidly by alternating the current five or six times during the sitting, and could use larger currents than without alternations.

Ten Milliampères Sufficient.—Dr. J. H. Gunning thought moulder's clay offered the best abdominal electrode. He liked platinum, and had found a way to beat instrument makers, who charged enormous prices for it. Buy a lightning-rod point, from which a good many platinum electrodes could be made. The negative pole was useful in relieving congestion. Instead of using thirty milliampères, he found five or ten sufficient. He could use a current of ten milliampères five minutes so as to destroy the surface of the uterus and enable one to remove the mucous membrane down to the connective tissue. This knowledge was obtained by comparative experiments. In view of these facts he never applied the metal electrode within the uterus unless to control hemorrhage; he covered it with clay, and thus brought the current in contact with the entire uterine surface with safety. The negative pole applied in that way would often reduce congestion in a very short time. To overcome pain, if the patient was thin and anæmic he used the bipolar faradic current; if plethoric, galvanism. Without the bipolar method, little would be accomplished in electrical treatment. He objected to large currents; 150 and 250 milliampères might cause one knew not what. He had known the whole interior of the uterus to be ulcerated after it. Where the positive pole was used, he saw no indication for the curette, unless indeed the electrode itself were made sharp and employed in that manner during the passage of the small current. By the bipolar method he could accomplish as much with five milliampères as could be accomplished with thirty where one electrode was placed on the abdomen.

The Darkest Therapeutic Agent.—Dr. H. J. Boldt thought electricity was the darkest therapeutic agent which we had. There were some conditions in which it would give most happy results, but generally when used in the pelvis it was employed blindly. It would in the majority of cases relieve pain connected with perimetric inflammatory conditions following laparotomy, the pain of oophoritis, and pain of indefinite origin. It was also of value after curetting in some cases of chronic endometritis, and it would relieve symptoms and diminish the tumor in some cases of fibroids. It should never be used in suppurating conditions. Since investigating the subject he had found that a number of deaths had resulted from it indirectly. As to patients bearing 200 milliampères in the uterus, he was astonished to hear the statement; even 40 or 50 were usually objected to in his experience.

Overestimated.—Dr. W. Gill Wylie had been unwilling to express an opinion of the value of electricity

until recently, for, although his experience with it dated back to the time when he was interne in the Woman's Hospital, he had not given it very careful study until the last three years. He knew of only one person who had used it in the Woman's Hospital when he was there who still made use of it. It was a curious fact that in no other department of medicine was this agent used in such a way or to such an extent as in gynecology. We did not hear of its employment against hemorrhage from the nose or elsewhere except from the uterus. He thought the reason why it was so largely recommended by some in gynecology was the fact that this department had not been treated of as intelligently as other departments of medicine. Even to-day the correct theory was not generally appreciated and put into practice. Almost all forms of subacute and chronic disease of the lining membrane of the uterus could be treated successfully by securing drainage and employing some alterative measure. He was satisfied that if we applied good surgery electricity would have little place. He objected in a most emphatic way to large electric doses within the uterus for the same reason that he objected to the older use of caustics like nitric acid, nitrate of silver, etc. They created sloughs and scars, destroyed the follicles and obstructed the glands, thus giving rise to reflex and all sorts of symptoms. Small currents would stimulate the undeveloped uterus; large ones administered by electro-puncture would cause fibroids to diminish in size, but might also cause them to slough. For his own part he could now remove a solid tumor with almost as great safety as a cyst, and in most cases where any treatment was demanded for fibroids he thought this a wiser course to pursue than to use electricity unless the patient especially demanded the latter.

Dr. P. F. Chambers said he had been very favorably situated for observing the results of electrical treatment during and after the course, and must admit to having seen very little benefit. He had seen a good many fibroids treated by electro-puncture and otherwise by electricity, but could not conscientiously say that he had observed marked improvement. The patient might be temporarily improved, but the result had altogether given little satisfaction.

Dr. G. M. Edebohls had used electricity alongside surgery for a year and a half, and while it had proved of some service, he did not feel very enthusiastic over it. He said there was scarcely any condition in gynecology which at present did not offer a choice for different plans of treatment, and electricity could at times be selected with advantage. As to the use of high currents, he felt no less anxiety in applying these within the uterus than in doing laparotomy. They should not be given by the general practitioner. In the first place, great diagnostic skill was required in determining when to use them. They were not without danger. In fibroids, one could not say that necrosis would not afterward take place from rapid diminution in size, lead to suppuration and death. He knew of one such case in the hands of another physician, and one in his own. In the latter not more than one hundred and seventy-five milliampères were used. The denudition had gone to the extent of causing softening of the fibroid, sepsis, and death, in spite of Freund's operation.

Dr. J. R. Goffe said that while in Paris he had heard Apostoli remark that the electricians in New York carried the treatment farther than he dared go. He sympathized with the remarks of Dr. Wylie.

Dr. Florian Krug cited some cases in which a diagnosis of fibroid of the uterus had been made and electricity advised, yet he found on operating that the tumor in one instance was a cysto-sarcoma of the ovary, and a double dermoid cyst in another; consequently electricity could only have resulted in harm. He had also operated for sepsis, arising from breaking down of a fibroid following the use of electricity by another physician, but it was too late, and the patient died.

Dr. Vineberg had seen Apostoli treat many cases, in none with bad results. He seldom had occasion to use very large doses, and did not repeat oftener than once in four or five days. In some he did employ 100 to 150 milliampères, but with no injurious consequences.

Dr. Malcolm McLean took a middle ground. He thought, with Dr. Wylie, that one must be a good surgeon to be a good gynecologist, and a good diagnostician to make right use of electricity.

Prefers Static Electricity.—Dr. W. J. Morton hoped gynecologists would test the value of static electricity, especially through his improved large Holt machine and outfit. He had given up faradic and galvanic electricity almost entirely in favor of static in nervous diseases. As to dissipating tumors by electricity, it could be done, in the case of surface tumors, at any rate, only by puncture.

Would Limit the Work of the Laparotomist.—The Chairman had found that the intelligent use of electricity would largely limit the field of the laparotomist. Where pus existed an operation ought always to be done, but in numerous other conditions all that was demanded was to relieve the patient of her symptoms, and certainly electricity did this in many instances where those who were not accustomed to its employment would perform laparotomy and expose the patient to mortal danger. He thought that those who condemned electricity most were frequently too busy with private, hospital, and dispensary practice to give it a fair trial.

Correspondence.

OUR VIENNA LETTER.

(From our Special Correspondent.)

THE THROAT CLINICS OVERCROWDED—MAKING THE ROUNDS WITH PROFESSOR BILLROTH—HIS FAMOUS PATHOLOGICAL SPECIMENS—CASES OF LUPUS CURED.

Vienna, January 14, 1891.

Vienna possesses the most trying winter climate in middle Europe. For the past three weeks the mercury has kept below 0° C., and heavy snow has fallen. There is much dampness and the skies are usually overcast. Such conditions, coupled with the malnutrition, insufficient clothing, and poor lodgings of the lower classes, make throat, nose, and lung diseases very prevalent. Among foreigners, also, catarrhal troubles are rife. The "Vienna throat" one hears of as soon as he arrives, and is well qualified to hand down the tradition to his successors when he leaves. It is questionable whether those who are at all predisposed to throat or lung disease do well to select Vienna for winter study.

All the throat clinics are overcrowded with material, which makes careful and systematic instruction difficult, Schnitzler, Störke, Schrötter, Uffinger, Chiari, Hajek, Berengscazy, and other teachers give courses, the attendance on which is eighty per cent. American and English. Where a given individual shall obtain most profit is naturally determined by his progress, needs, and in short the personal equation. In some clinics the instruction is elementary. In others, the students do such operations as removing tonsils, cauterizing the nose, and extirpation of laryngeal growths.

No notice of throat study here would be complete which ignored the distinguished usefulness of one Frau Gailey, a ward employee in Professor Schrötter's clinic. Though at least sixty, and though she has lost one eye, this person exercises a marked fascination over all young students. The charm lies in the remarkable tolerance of instruments and foreign bodies which her larynx has by long practice acquired. Her occupation has thus come to be that of an animated manikin. For one gulden (40 cents) and a glass of wine she permits the

student to introduce instruments, place and remove foreign bodies, etc., by the hour. So skilled is she that the operator's mistakes are corrected by her hand directing his till the right spot is touched.

One of the interesting experiences here is to make the rounds of Professor Billroth's wards with the great surgeon himself. The Professor walks with a slight stoop, and usually with his hands behind him, and he and his assistants are clad in long operating coats precisely like linen dusters, which with the old and more or less shabby surroundings renders the *ensemble* anything but distinguished. But an hour with this strong, calm, self poised personality, whose low-toned utterances give the results of a lifetime of wonderful industry in the richest fields, leaves a deeper impress than many more showy experiences.

Much use is made here of perpendicular extension in treating fractures of the femur in children. The ordinary plaster strips are bandaged to the limb, but instead of the cord which attaches the weight passing horizontally over a pulley at the foot of the bed, it passes perpendicularly over one directly above the patient's pelvis, thence horizontally to a second, and then to the weight. This latter is just sufficient to raise the buttock of the affected side clear of the bed. The whole limb and half the pelvis is thus swung at right angles to the trunk. Thus defecation can be easily managed and perfect cleanliness secured. No coaptation splints are employed, and no device for preventing rotation. It is found that a muscular equilibrium is quickly established, which prevents inversion or eversion. Results are excellent.

In plastic surgery remaining defects are closed by Thiersch's method of skin transplantation. With a razor-edged knife strips of epidermis some five by two inches are shaved evenly from the thigh, and applied over the raw surface—superfluous parts being trimmed away. The corium is but slightly included in this paring, and quickly recovers itself, while the transplanted flap almost always adheres.

Well worthy of a visit is the Pathological Museum attached to Professor Billroth's clinic. Here are the specimens of pylorus resection from the first operation to the present. Overhead hang, like Chinese lanterns, rows of dried, inflated ovarian cysts. On the shelves are the trophies of many triumphs, among them a large collection of foreign bodies removed by enterotomy. This operation is but seldom needed now. An adult who has swallowed his false teeth, or a child who has similarly made way with a spoon is simply fed potatoes. Fried, baked, boiled, or roasted, they form his only article of diet, and accumulation is favored by occasional doses of opium. This treatment was first empirically used, we are told, by London thieves to recover articles of value which had been stolen and swallowed. It has in Billroth's clinic removed foreign bodies, which in subsequent experiments on the cadavers of subjects of like age and size could not be forced through the alimentary tract.

In the wards one sees many cases of lupus and surgical tuberculosis which have been treated by Koch's injections. In two of these satisfactory healing has been secured, and Professor Billroth will shortly proceed to correct the nasal deformity in one case of cicatrized lupus, by plastic operation.

In the meanwhile, clinical experimentation with Koch's lymph proceeds, and results are being slowly obtained, which, if not definitively curative, are at least superior to any heretofore gained by other means. Professor Kaposi has produced marked improvement in a goodly number of lupus cases, and in two or three complete cicatrization has ensued. Nodules are still to be felt under the scars, but active ulceration has ceased. In many of the unimproved cases a tolerance of the remedy has been established so that even 0.07 produces no effect. It is proposed to cease treatment for a time, in expectation that this tolerance may pass away, and then to begin anew with minimal doses.

AN OLD SURGICAL BILL.

To the Editor of the Medical Record.

Sir: On page 364 of volume ii., of the "Documentary History of the State of New York," Albany, 1849, appears

Dr. Thornhill & Dr Kelsoe's Bill.

An accompt ffor the Wounded & those Men that were Killed in their Majesties Service against Leisseler and his accomplices

	£. s. d.
To Richard Grenard Saddler ffor curing him a gun shot wound through both hips	15.00.00
To James Yeward for curing him of a wound in the shoulder & cutting the bullet out amongst his ribs	15.00.00
To attendance upon Mr. Joseph broune in a gun shot wound	00.10.00
To attendance upon Mrs. Depeysters negro of a gunshot wound	02.10.00
To weiuing the Bodie of Major Mcrigorie	01.00.00
To weuing the Bodie of Mr Pecay	01.00.00
To weuing the bodie of Wessell ten broeke	01.00.00
To weuing the bodie of Leonard Beckwith	01.00.00
To weuing the bodie of Joseph Broune	01.00.00
To weuing the bodie of Mrs. DePeysters negro	01 00.00
To the curing 1 of his Majesties Souldiers of gunshot wound through both the Humerus & radius	10.00.00
	49.00.00

This bill bears no date, but it was probably audited in April, 1691. Lieutenant-Governor Jacob Leisler was captured at Fort William, New York City, March 20, 169$\frac{0}{1}$, but the account of the capture and trial leaves us in doubt whether the killing and wounding were done at the time of the capture or during the previous contests.

Was this "weaving the body" a form of embalmment? What was the process?

Yours very respectfully,

Charles E. Slocum, M.D.

Defiance, O.

VERY BAD IF TRUE.

To the Editor of the Medical Record.

Sir: I desire in this brief note to call off the attention of the enthusiasts of the profession from Koch's lymph, and all other such things, to the plain pathological fact, that genuine tuberculosis is a malnutrition, the natural result of a defective organization, and therefore absolutely incurable. In other words, the victim of this disease is not made right in the beginning, and hence can only be cured by a new creation process. It is the result of defective organization either hereditary or otherwise.

Very respectfully, yours,

J. S. Prettyman, M.D.

Milford, Del.

THE GERMICIDAL ACTION OF THE BLOOD.

To the Editor of the Medical Record.

Sir: In view of the fact that medical science is attaching unusual signification to the discovery of the "germicidal action of the blood" I desire to direct attention to that portion of its origin and history connected with my observations made several years since. Metschnikoff and his theory of the phagocytic action of cells has attracted universal notice and has brought its distinguished propounder a deserved fame. At present there is a disposition generally prevalent which is inclined to look upon the discovery of the germicidal powers of the blood as of far greater importance than that of the noted Russian; yet as to whether it shall eventually supplant or only supplement his services remains to be seen. Be this as it may, my sole purpose here is to ascertain, if possible, to whom the credit of first suggesting this function of blood belongs. Without arrogating this distinguishing fact to myself as author I do maintain that I advanced this doctrine, independently and originally, so far as I know, as far back as September, 1887, while preparing the MS. for the article "Race" in Wood's Handbook, vol. viii. page 430, where I employed the following language when

discussing the factors which go to determine the conditions of immunity and susceptibility among the various races and nations of the world: "Whether the active mediums of resistance be chemical substances, the activities of the cellular tissues, or the white blood corpuscles, or all of these in combination, we know that the investigations of Maurel show the blood of the different races presents differences of composition and number of cells. . . . How far these discrepancies are to be taken in explanation of the various degrees of immunity and susceptibility that are found to characterize the various people of the world is a question still demanding further inquiry. Viewing 'the blood as the life' and that a capacity to resist any and all diseases of this class —infectious—is proportional to its perfectness in composition, it can readily be seen that the blood may also act the part of a protecting agency—one capable of thwarting the assaults of the pathogenic micro-organism." I base my pretensions to priority upon the date of September, 1887, when, so far as I am aware, no author had suggested or discovered the germicidal action of the blood. If I am wrong I should be happy to be corrected. Respectfully,

J. Wellington Byers, M.D.

Charlotte, N. C.

New Instruments.

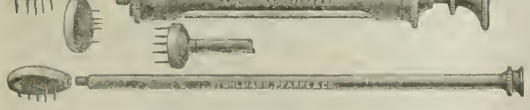
SUBMEMBRANOUS MEDICATION IN THE TREATMENT OF DIPHTHERIA.

By LOUIS FISCHER, M.D.,

ATTENDING PHYSICIAN TO THE CHILDREN'S DEPARTMENT OF THE GERMAN POLIKLINIK.

Chlorine, and more particularly chlorine water, has long been known for its stimulant and antiseptic qualities. Dobie, in 1866, found it more effectual than any other drug in the treatment of diphtheria (*Edinburgh Medical Journal*). Dr. Althaus, in 1868, in an epidemic of diphtheria in Germany, speaks very highly of it (*Medical Times and Gazette*, July, 1868).

Ringer's "Therapeutics," p. 97, speaks very highly of chlorine and its compound, chlorinated soda, in malignant sore throat. Henoch recommends its internal administration, combining it with decoct. chinæ, and so, in all the latest works, chlorine is extolled more or less as a valuable remedy. Dr. Unger ("Lehrbuch der Kinder-Krankheiten," 1890) speaks well of the internal administration of aqua chlori, and so numerous other writers.



Not, however, until recently, December, 1890, has a newer method been recommended by Dr. Seibert, of this city, who employs chlorine water by means of a hypodermic syringe having a long nozzle ending in several points, and by introducing these into the diphtheritic membrane has carried the chlorine into the submembranous tissues, claiming very good results.

Through the kindness of Dr. Seibert I was enabled to use his instrument in a typical case of diphtheria.

Case I.—Servant girl, aged twenty-two. She had been infected by a child, which had died the day previous to her first symptoms, and although her temperature was but 102.2° F. in the evening, she appeared greatly prostrated and complained of violent pains in the muscles of her body. I gave her a subcutaneous injection of five minims of chlorine water into the left tonsil, and was surprised to find her almost recovered by the next evening. She had a very large membrane, which loosened after the fourth day of treatment; she receiving nothing but five-minim injections of chlorine water, and general stimulation, whiskey and milk. I discharged the case cured on the sixth day after the first injection.

Case II.—Child, six years of age, had been sick; complained of dysphagia; on examination I found both tonsils covered with diphtheritic membrane; temperature in rectum 104° F. I gave child gtt. iij. of the officinal aqua chlori hypodermically, directly into the diphtheritic membranes, and found the temperature 102° F. in the evening of the same day. I continued using gtt. iij. hypodermically for four days. Child was discharged cured.

Case III.—Patient aged thirty; diagnosis had been confirmed by a prominent laryngologist of this city. This patient was nursed very carefully, and everything noted. The left tonsil was first affected, after which the right tonsil showed pseudo-membranes. I commenced by giving gtt. v. aqua chlori, and although the severe muscular pains which patient complained of in thighs was not much relieved, the diphtheritic membranes seemed to fade away. This patient finally developed a diphtheritic uvulitis, and later a pharyngitis diphtheritica. I noticed, however, that the violence of the attack and the temperature almost subsided after twelve hours from the first submembranous medication.

Finally, I must state that this form of treatment is not adapted for naso-pharyngeal diphtheria, but that in the few cases, six in all, where I have used it in diphtheria affecting either tonsil or the pharyngeal wall it has given me satisfaction, and it is well to try it.

Nor have I used the chlorine water 0.2 per cent. solution, but have resorted to the officinal preparation, aqua chlori of the U. S. P.

Owing to the gaseous properties of chlorine water it is advisable to use only a freshly prepared solution.

40 Rivington Street.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 1, 1891, to February 7, 1891.

Davis, William B., Captain and Assistant Surgeon. The leave of absence for seven days granted by Orders No. 2, Fort Preble, Me., February 4, 1891, is hereby extended twenty-three days, with permission to apply to the Adjutant-General of the Army for a further extension of one month. S. O. 22, par. 2, Headquarters Division of the Atlantic, Governor's Island, N. Y., February 5, 1891.

Chapin, Alonzo R., Captain and Assistant Surgeon, Fort Yates, N. D. Granted leave of absence for one month, with permission to apply to the Adjutant-General of the Army for an extension of one month. S. O. 17, par 3, Department of Dakota, St. Paul, Minn., January 31, 1891.

De Witt, Calvin, Major and Surgeon. By direction of the Secretary of War, is relieved from duty at Fort Hancock, Tex., and will report in person to the commanding officer at Fort Sam Houston, Tex., for duty at that station. S. O. 27, par. 1, A. G. O., Washington, D. C., February 3. 1891.

Stephenson, William, Captain and Assistant Surgeon. By direction of the Secretary of War, will proceed without delay from Columbus Barracks, O., to Fort Wayne, Mich., and report in person to the commanding officer of that post for temporary duty, and upon the completion thereof will return to his proper station. S. O. 23, par. 13, A. G. O., Washington, D. C., January 28, 1891.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 7, 1891.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	11	2
Scarlet fever	153	20
Cerebro-spinal meningitis	3	2
Measles	447	13
Diphtheria	121	30
Small-pox	0	0
Varicella	6	0
Pertussis	1	9
Croup	0	0

Resection of the Urethra for Traumatic Stricture.—A case in which resection of the urethra for traumatic stricture proved successful is recorded by Dr. Horteloup. The patient, aged nineteen, had an impassable traumatic stricture at the level of the perineum. The whole of the contracted portion was excised, and a month afterward a No. 50 Béniqué bougie could be passed easily. After six years and a half the result continued good. The resection of the urethra is easy, and thanks to antiseptic methods is not more dangerous than external urethrotomy. The formation of a urethral fistula need not be feared unless the stricture is in the spongy portion. Dr. Horteloup does not recommend resection in all cases of stricture of urethra, but only as a remedy for traumatic stricture, as in these cases a relapse is the rule.—*Le Progrès Médical.*

The Chicago Academy of Medicine.—A charter has recently been granted to a new medical society in Chicago to be known by this name. According to the *North American Practitioner* there is need of another medical society in that city. The Chicago Medical Society, it says, does not satisfy the aspirations of the profession in that town. Its meetings are held in a dirty and noisy club-room in the Grand Pacific Hotel, in order to reach which the members are compelled to pass through the bar-room, and thus wantonly expose themselves to temptation.

Statistics of Lymphadenitis.—Dr. W. W. Van Arsdale, of this city, writes: "In your report of the meeting of the Academy of Medicine of January 15th, in the discussion on lymphadenitis, I am quoted as saying that I had seen 55 cases of lymphadenitis during the past year. It should be 555. Since any statistical statement in regard to lymphadenitis, based upon so small a number as 50 cases would appear almost valueless, I may add that my statistical statements were actually based upon 1,581 cases observed and treated by me, an equal number to that of last year having been seen by me in dispensary practice for the last three and a half years. May I ask you to have the error corrected?"

Careless Speech and Children.—If we stop to think how every word spoken in the presence of a little child affects its future for good or evil, we would all be far more considerate in our speech. It is astonishing how children will ponder for days a careless word or sentence which no one supposed they had even heard, and at some critical moment use it themselves with a most startling and horrifying effect. Then, alas! we see and deplore its real deformity, and realize how potent is our influence over these observant innocents!

The Geographical Pathology of Europe.—The following list of diseases prevailing in different countries of Europe, translated from *La Rivista Internazional d'Igiene* for the Marine Hospital Bureau, appears in the Abstract of Sanitary Reports, for September 12, 1890.

An Industrial Use of Microbes.—Dr. Neilson, of Norway, says that the Norwegian fisherfolk have for more than five hundred years used pathogenic bacteria in catching whales. A few miles from the town of Bergen there is a narrow inlet of the sea into the mouth of which whales make their way every season. When a whale is discovered in this place the alarm is given and the fishermen put out in their boats, drive the whale farther up the narrow bay, and stretch a net across the mouth of the inlet. Through this the monster could easily break, but he does not. Then they proceed to capture him and bring him to land. The animal, however, is twenty or thirty feet long and very strong, and with their primitive implements alone this cannot be done. They therefore inoculate the whale with the poison of an infectious disease, and only after he is weakened as the result of the disease do they try to kill him. After the whale has been enclosed, the bowmen put out, and when he comes to the surface to breathe, they shoot infected arrows into him and withdraw. After twenty-four or thirty-six hours, the whale becomes less lively in his movements and comes to the surface often to breathe. Then the real battle begins, and after driving ten or twelve harpoons into the whale, the fishermen are able to land him. An examination of the places where the arrows were shot into the whale shows, in the immediate vicinity of some of them, a hemorrhagic infiltration of the muscular tissue, resembling very much the disease of land animals called sympathetic anthrax. The internal organs are normal; once only Dr. Neilson found a bacillus in the blood-vessels of the spleen. Around the poisoned wounds vast numbers of a bacillus are found closely resembling that of sympathetic anthrax. When the arrows are pulled out of the wounds, many of these bacilli cling to them, and thus render them effective as "death arrows" when further used. And thus the catching of whales goes on year after year, and has gone on for five hundred years. Dr. Neilson inclines to the opinion that the infection is the same as that of sympathetic anthrax, and hopes that later investigations may clear up the point.—*Sanitary Inspector.*

TRANSPLANTATION OF TISSUE FROM LOWER ANIMALS TO MAN,

AND A REPORT OF THE CASE OF BONE-TRANSPLANTATION AT CHARITY HOSPITAL, BLACKWELL'S ISLAND, N. Y.

BY A. M. PHELPS, M.D.,

[NEW YORK.

THE case of transplantation from an animal, recently performed at Charity Hospital, has commanded a wide-spread attention and all sorts of absurd rumors have been circulated. But, as will be seen by the present recital, none of the real facts have been stated. The operation is a success in so far as it establishes the principle that it is possible to grow large masses of tissue from an animal to man, and to establish the circulation until the union takes place between opposite species without danger to either. It also demonstrates that a growth of new bone takes place when a section of bone is transplanted and its nutrition maintained by the artery of the animal. This, if continued for four or five weeks, would probably unite a fracture. Owing to the inefficient dressing, which is

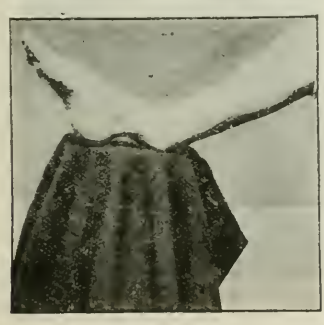

FIG. 1.

apt to occur in all early operations, the contact of the transplanted bone could not be continued sufficiently long for bone to unite to bone. But I am confident, after viewing the specimen, and taking all the conditions and surroundings into account, that bony union would have taken place if actual contact could have been maintained for a longer period. The stimulation of the graft, however, has excited a reparative process in the fracture, and it now promises fair to unite. The boy walks with the aid of one crutch or a cane.

In October a case of ununited fracture of the leg was referred to me by Mr. Marks, the artificial limb manufacturer, and subsequently by Dr. Shufelt, of this city. The patient came here for amputation and an artificial leg. He had been twice operated upon by an eminent surgeon, with a failure each time.

Fig. 1 is made from a photograph, and represents the deformity; Fig. 2 illustrates the positions of the bones, the fibula being some two inches longer than the tibia. I refused to amputate and suggested the operation of bone-transplantation from an animal.

Observation made in my studies during the past two years convinced me that the circulation between opposite species could be established with safety.

Figs. 3 and 4 are reproductions of drawings taken from Billroth's "Pathology." Fig. 3 is from a simple incised wound, showing the effusion of blood into the wound and the capillaries. Fig. 4, the capillary loops growing into the new cell-formation. These finally unite and the circulation is established between opposite sides of the wound. The interchanging of blood between opposite species whose corpuscular elements differed in size, introduced a serious question. But it was reasonable to suppose that the dog would construct capillaries of natural size which might be a little larger than those of the patient. This would prevent the corpuscular elements of the blood from entering the

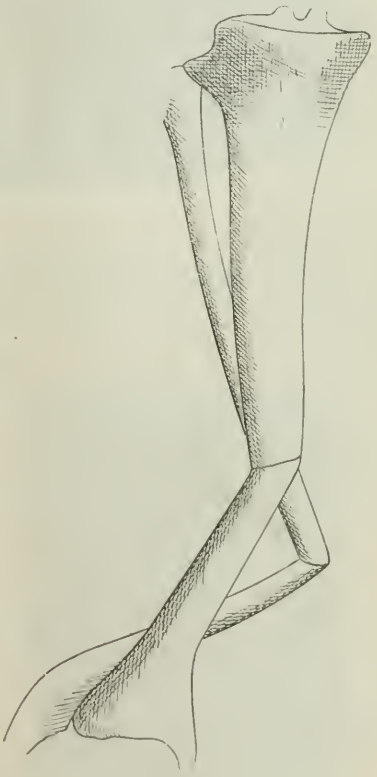

FIG. 2.

capillaries of the patient, and then, secondly, the corpuscles, being protoplasm and possessed of amœboid powers, would accommodate themselves to the smaller capillaries of the human being, and not be arrested in the circulation of the brain or other internal organs. If contact could be maintained bone ought to unite to bone as kindly as muscle to muscle or skin to skin—a fact which I had already demonstrated. The conditions favorable for the union being absolute rest of the wound, perfect coaptation, thorough drainage, and scrupulous

cleanliness combined with antisepsis. In my clinic at the Post-Graduate School and Hospital I performed the operation in the presence of the medical class and a few members of the faculty.

The patient and the dog did well. Upon the sixth day I discovered that the contraction of the biceps muscle had tilted the bone graft up into the wound. Inefficient method of securing the bone in place and the neglect to detach the tendon of the biceps muscle had defeated the operation. The graft was removed. I found

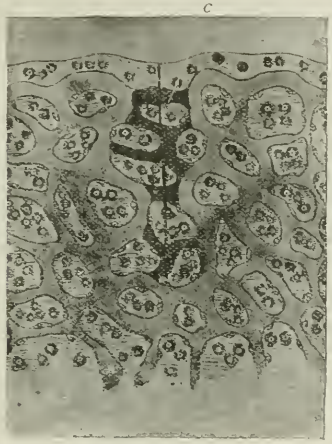

Fig. 3.

that firm primary union had taken place between the soft parts, and considerable force was required to detach the graft. The limb was subsequently amputated and an artificial one adjusted. Thus ended the first case.

In the month of November, last year, the patient at Charity Hospital was sent to me for operation. Briefly the history of the case is this:

The lad, John Gethins, was suffering from an ununited

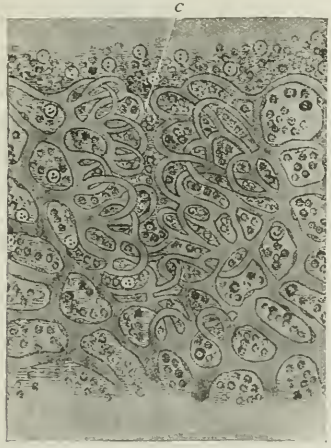

Fig. 4.

fracture of the lower third of the leg, the result of an operation to remedy an anterior curvature of the tibia, which had existed and had slowly increased from early childhood, until he was compelled to go upon crutches.

Fig. 5 is a photograph of the case before the operation of osteotomy. There was no paralysis of the limb, neither was it atrophied, excepting from non-use. The muscles were perfect in every respect.

This case was referred to my clinic, two years ago, by Drs. Wey and Flood, of Elmira, and Dr. Bush, Assemblyman of Horseheads, who kindly furnished the money to pay the patient's expenses while in the hospital.

A few months after the operation of osteotomy I cut down upon the fracture and wired it, but failed in getting union. After a few months I again operated, removing all cicatricial tissue, carefully stitching the periosteum together, and wired the bone. This failed. A few months later I again cut down upon the fracture, removed all cicatricial tissue, and again freshened the ends of the bone, and engrafted decalcified bone chips, according to Senn's method. This failed; the chips came away from the wound a few weeks after the operation. I then resorted to Thomas's method of hammering, damming, and adjusting an appliance for the boy to walk upon. This he wore for several months, but again we failed to secure union.

In the meantime the boy had returned to his home. From time to time I received letters from the lad, beseeching me again to make an effort to restore his limb to usefulness and avoid an amputation. He returned again to New York and was referred to one of the

Fig. 5.

largest and best hospitals in the city; and one of the most eminent surgeons of this country operated upon him twice, with a failure each time. The poor boy, discouraged, returned to his home again.

Last fall, in October, I received a most pathetic letter from him, asking if I would again attempt to unite the fracture. A letter was written to him stating that an attempt at bone-transplantation from a dog, of which I had previously told him, would be tried if he desired. In answer to the letter his parents at once sent him to New York. He was sent to Charity Hospital. The limb, at the time of the operation, November 16, 1890, was in very good condition, excepting the shortening of about four inches, the result of previous operations which had been performed to unite the fracture.

It seemed a pity to amputate the leg. And surely we had arrived at that stage of the case where, so far as our present knowledge was concerned, amputation was the last and only step to be taken. With all of these facts before us we felt perfectly justified in attempting any experiment which would promise to succeed in restoring the limb to usefulness, provided the danger to life was not too great.

The brave lad had submitted to every means known to surgery for the relief of his condition, and, discouraged

and heart-broken, had returned to his home. When he was told there was another chance for his limb his face brightened and he said, "Doctor, I will take that chance." After consulting with the members of the Medical Board of Charity Hospital and several eminent surgeons of this city, we decided upon an operation.

It is a well-known surgical fact that an amputation performed in the growing limb below the knee, or in the humerus, frequently results in what is known as a conical stump. This necessarily leads to re-amputation, and many amputations have been performed from year to year in the same cases for this abnormality. This was one of the reasons, but not the greatest, why we hesitated to amputate the limb.

A dog two years old was secured and prepared for the operation, carefully cleansed with soap and water and made aseptic with a solution of bichloride of mercury.

While the patient was being anæsthetized and the ends of the fractured bones freshened my assistants, Drs. Plympton and Mooney, prepared the dog in the following manner: She was etherized, and then enveloped in a thick layer of absorbent cotton to the thickness of several inches while placed in the natural sitting posture. Over this soft covering of cotton a few turns of a plaster-of-Paris bandage were made to hold the dressing in place. The dog was not encased in plaster of Paris; the right foreleg of the animal protruded through the dressings.

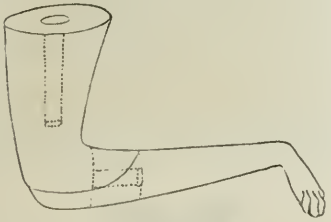

Fig. 7.

This leg was carefully shaved and again made aseptic with bichloride of mercury, and finally with iodoform and ether. The dog was now ready for the operation. With the assistance of Dr. James E. Kelley, Visiting Surgeon to Charity Hospital, and also Drs. Charles D. Roy, C. Stephenson, and J. D. Wood, members of the house staff, we proceeded to the operation upon the patient, which was performed before the matriculates of the Post-Graduate School and Hospital. There were also present Dr. Huntington, of Sacramento, Cal., and Dr. J. F. Winn, of Richmond, Va., and the hospital staff. No one else was present.

Two elliptical incisions were made down to the fracture, four inches in length, removing the old cicatrix and cicatricial tissue about the ununited ends of the bone, together with an elliptical piece of the soft parts. With a saw the ends of the bones were freshened, leaving a space of about one inch between them. The portions removed proved to be eburnated and more like ivory than bone.

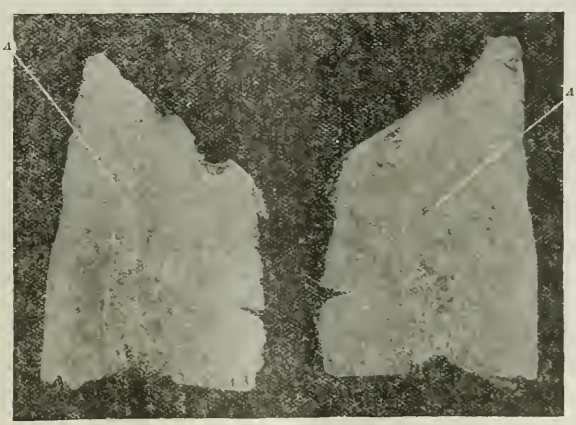

Fig. 6.

Fig. 6 is taken from the photograph of the specimen. *A*, *A*, shows the canal filled with solid bone. My assistants, Drs. Plympton and Mooney, now prepared the limb of the patient for the next step in the operation, by enveloping it in a plaster-of-Paris bandage, commencing six inches above the incision and extending to the upper third of the thigh. The foot and ankle were also covered with a plaster-of-Paris bandage. While they were skilfully preparing this part of the dressing we were preparing the dog. An incision was made through the skin, as represented in Fig. 7, for the purpose of cutting a piece which would accurately fit in the elliptical shaped wound of the patient's leg. The elbow was now quickly excised; the radius and ulna were severed one-half inch in front of the elbow-joint, and the humerus three inches above it, and removed (see Fig. 8, *B*), leaving all the soft parts.

The extremity near the paw was amputated, leaving a piece of bone one inch in length (Fig. 8, *A*), attached to a branch of the brachial artery among the soft parts.

The attachment of the biceps tendon was detached from the bone and loose superfluous muscular tissue removed. In the dog the nutrient artery enters the bone one inch in front of the elbow-joint. Cutting the bone, as indicated above, saved the nutrient artery from injury and secured the nutrition to the fragment of bone from which we had hoped that new bone would be thrown out, and at the same time stimulate the human bone to a reparative effort.

The dog was placed by the side of the patient's leg, the head toward the patient, Fig. 9.

An aluminum dowel pin was passed through the medullary cavity in the long axis of the bone. This I think was a mistake. A steel pin inserted into the solid portion of the bone would not interfere with circulation so much. See Fig. 10. The piece of bone *A*, Fig. 8, was placed between the ends of the bone *B*, *B*, of the patient, as seen in Fig. 11. The bones were crowded together, the dowel-pin entering the bones of the patient above and below. A silver wire was passed around the entire graft (see Fig. 11) and securely tied. This held the bone firmly in place. Fig. 11 shows the artery giving off its nutrient branch to the grafted bone, *A*. Muscle was stitched to muscle, and skin to skin, the parts being evenly coaptated. *C* is the humerus of the dog.

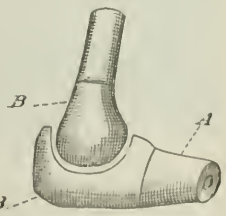

Fig. 8.

Fig. 12 is a diagram showing the bone, *A*, in place between the bones of the boy, *B*, *C*. It also shows the dowel-pin, wire, main artery, and nutrient artery. *D* represents the dog's leg stitched to the soft parts of the patient, *E*. Band iron was bent and adjusted over the wound, from the upper plaster cast to the lower one of the boy's foot, thus leaving room for dressing. A large drainage-tube was inserted for drainage, which opened posteriorly.

A few turns of the plaster of-Paris bandage secured the iron rods to the leg. The wound was dressed antiseptically.

Through the entire operation the most rigid antiseptic methods were carried out. Constant irrigation prevented the possibility of wound infection. Having in Drs. Plympton and Mooney two most efficient dressers, and working two teams, one for dressing and one for operating, the hands of the operator did not need to come in contact

Fig. 9.

with the plaster of Paris or septic dressings. The operation can be performed in one hour with efficient dressers.

The operation appears difficult and complicated, but is quite simple when understood. Many mistakes of the first operation were corrected in this, and many which occurred in this could be corrected in another. The operation of open incision for club-foot, which I first performed in 1879 and published in 1880, was perfected only after twenty operations had been done. And so it is with all first operations involving complicating mechanics.

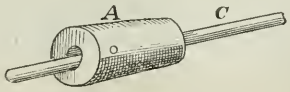

Fig. 10.

The patients (for we must now say patients) were put

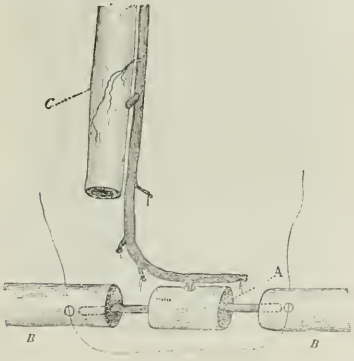

Fig. 11.

to bed. Both recovered from the anæsthetic rapidly. Small doses of morphine were used for both, from time to time, to allay, not so much the pain as the uneasiness caused by the forced confinement. After three days this uneasiness passed away, and from that time on the dog and patient became friends, administering to each other's comfort—the patient by feeding and playing with the dog, and the dog by vigorous wags of the tail which showed her appreciation of his kindness.

I neglected to say that before the operation was performed the vocal cords of the dog had been carefully severed, under ether, to prevent any disturbance of the patient. At the end of two weeks, however, the cords had again reunited, and the voice of the dog sounded fully as strong as before the operation. The only pain caused to either patient was the twitching of the muscles of the dog as she shrank in her bed from the loss of adipose tissue. This might have been prevented by a simple procedure at the time of operation. But this was a new development which had not occurred in the first case, and which we were not fully prepared to meet when first discovered in this.

On the sixth day the case was dressed in the presence of Drs. Newman, Stewart, Wooley, and Professor Prince Morrow, of the University Medical College, and Visiting Surgeon to Charity Hospital.

The wound was found perfectly healed by primary union, without a single drop of pus. Only for the difference in the color of the skin it would have been difficult to detect the line of union. On the eighth day we again dressed and the union was still perfect and more firm. Finally, at the end of eleven days, there was an apparent shrinkage of the dog in the dressings. This allowed of motion, and it became evident that the graft would be pulled from its attachment within a few days. Consequently, much as I desired to continue the experiment, I concluded, as a prospective act of humanity, to sever the bond of union. I was prepared to do this the moment that I discovered that any surgical interference would become necessary, which would inflict additional pain to either, in order to continue the experiment.

The dog was chloroformed during the operation.

While the graft was being trimmed, and the leg of the patient dressed, Dr. Kelley skilfully secured the artery and nicely stitched up the stump of the dog's leg. She was then placed in bed and cared for by the nurse. As the graft was trimmed down to the parts still attached a free oozing of blood took place through the graft, which demonstrated the fact that union had taken place and

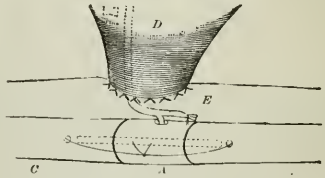

Fig. 12.

that circulation had been established between the patient and the dog. Both patients rapidly convalesced. The boy spent his time writing letters to his friends and reading the papers and postal cards from persons praying that the effort to save his leg might be a failure.

The wound was dressed and the graft examined daily. At the end of five weeks it was discovered that the bone showed no further sign of uniting, and desiring to give the boy every chance for union of the fracture it was removed. The rods, also, were removed, and the ends of the patient's bones placed firmly together, hoping to secure union because of the stimulation produced by the graft. The bone-graft was irregularly covered with a new growth

of bone, as seen in Fig. 13, *B*, thus proving, I believe, that an effort had been made to unite the fracture.

This was the result of eleven days' contact, whereas at least thirty days are required for bony union to take place.

Fig. 14 is taken from a photograph of a longitudinal section of the same bone and shows the thickness of the new growth on its surface, *A*. The canal of the bone was

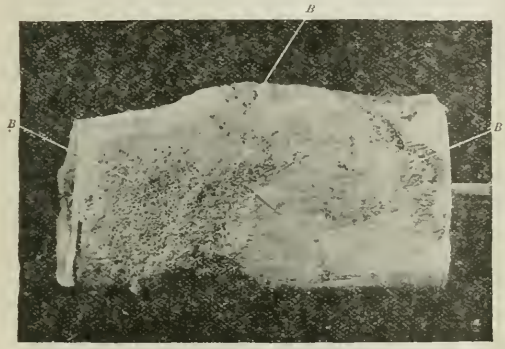

Fig. 13.

also filled with new growth of bone, excepting where the dowel-pin passed through.

The average temperature recorded in the patient was about 99½°, in the dog 99⅘° F. The average pulse of the boy was about 95; that of the dog about 98. The normal temperature of the dog is above a hundred degrees, that of the human being 98½° F. The temperature of the dog fell to below a hundred and that of the boy rose to near a hundred, or the same as that of the dog, where it remained for weeks. The pulse of the boy rose and the dog's fell until they beat nearly the same number of beats per minute, varying from ninety to one hundred and ten. The boy ate, slept, and felt well. There was no sepsis. Whether this peculiar condition of temperature and pulse was due to the interchanging of blood between the animal and the patient I am unable to say; further observation is necessary to verify it.

Fig. 9 is a photograph of the case taken by Dr. R. H. Pomeroy, a member of the house staff, a few days after the operation. After the eleventh day, owing to the plaster of Paris accidentally getting into the wound, pus for the first time was seen. This rapidly disappeared.

The operation had a twofold object: First, to establish the fact that large masses of soft parts could be transplanted from an animal to man; second, to unite an ununited fracture by a section of bone from the dog. We have succeeded in demonstrating the first proposition, but have partially failed in the other in so far as the actual growing of the bone into place is concerned. This was due entirely to a defect in the dressings. This principle of transplantation established means much to humanity; its application will be found useful in many cases which now defy the best efforts of the most skilful surgeons in the world.

Among the cases suitable for the application of the principle are those cases of fractures which resist all efforts for their union, and which must necessarily result in amputation; ulcers of a particular class which can be cured by no means known to surgery; scalps ripped from the heads of factory girls by machinery. Months, and often years, have been taken to skin-graft back the scalp to cover the skull, and numerous friends have been flayed to supply the material.

Thiersch's method of skin-grafting has been a step in advance of the older methods, but a martyr must be found to submit to the flaying. A dog would be found better adapted for the work, as hair could be transplanted with the flap. Sloughing, following amputations in the upper third of the tibia, resulting in cicatricial contraction with indolent granulations covering the end of the stump, caused by the bad circulation from pressure, is now cured. But how? By amputation at the knee-joint or else so near to it that an artificial limb cannot be worn with a useful knee-joint. Animal transplantation should be resorted to before amputation is performed.

If circulation could be established between opposite species, the elements of whose blood differed, without injury to either, a step would be taken which might lead to the relief of many a sufferer. Then large masses of tissue could be grafted from an animal to man, the circulation of the animal furnishing that which the patient could not supply, as in bone-transplantation. Or in grafting of soft parts the circulation of the dog would keep alive the graft until it had become firmly united to the patient, then it could be severed.

In bone transplantation it was expected that in four or five weeks the animal would have thrown out a provisional callus, and at the same time stimulate the fracture to repair. Figs. 13 and 14 seem to substantiate that theory. A dog was selected because the elements of its blood very closely resemble those of man. The reparative energy of a dog is very strong and his power of endurance great. No unnecessary cruelty is inflicted, and aside from the confinement but little suffering occurs.

Of course it is useless to reply to those who have denounced the operation as cruel and unnecessary. Those who understand the motive which actuates the surgeon can comprehend how, with all sympathy for the brute, his sacrifice of limb may be demanded for the good of his master, man. They, too, can appreciate the reluctance of the surgeon to inflict wanton suffering, whether upon man or brute, and can understand how such an operation only seemed commendable when a more than commensurate benefit was promised. To those whose eyes are blind to

Fig. 14.

human suffering, and whose sympathies are all for the brute, I have nothing to say.

It will perhaps be remembered that this poor lad demanded that every means should be exhausted which promised relief before amputation should be resorted to. He still demands it, and the demand is one which a humane surgeon should consider before resorting to an operation which would involve the loss of a limb and possibly life.

The Central-Zeitung fur das Koch'sche Heilverfahren, the organ for the progress in curing tuberculosis and other infectious diseases, has just appeared in Berlin.

A CASE OF ACUTE ASCENDING PARALYSIS—RAPIDLY FATAL ISSUE.

By JOSEPH EICHBERG, M.D.,

CINCINNATI, O.

THE case whose history I desire to report to-day is one of more than usual interest; its comparatively rare occurrence, the difficulty of diagnosis, and the speedily unfortunate termination entitle it to more than a passing notice.

The autopsy and the subsequent microscopic examination of the central nervous structures were, in a measure, necessary to clearly establish what had been, before, a somewhat doubtful diagnosis.

The question had been raised, shortly after the admission of the patient to the service, whether we were dealing with an acute inflammatory process of the cord, or whether this might not be a case of so-called Landry's paralysis, a term that still lacks scientific limitation, and for which no precise clinical picture has yet been presented. Aside from the question of diagnosis, the decision of this question was of some importance as to prognosis, the chances for the patient being a trifle better with a myelitis than with an attack of Landry's paralysis. The points of resemblance and difference will appear pretty clearly from the following history, for the careful notes of which I am indebted to Dr. Hunter, interne of the service.

Supposing it to be Landry's paralysis, the suddenness of the attack, the rapidity of its march, and the quickly

FIG. 1.—Anterior Horn, Gray Matter. Lumbar enlargement, showing pericellular lymph-space very plainly, owing to placing cord in alcohol for twenty-four hours before transferring to Müller's fluid. 60 diameters. Normal cord.

supervening fatal issue would earn for it a qualification which the French have found in the pertinent adjective *foudroyant*, as though struck by lightning. It is not the least singular feature of this disease that, mysterious as it is in onset, baffling in progress, hopeless in treatment, it yet should fail to show to the most careful examination, by scalpel and microscope, the track which marks the path of the storm.

We pride ourselves on increased resources in the great field of pathology; yet this is a section where the soil has but been turned; and there are, indeed, few affections, concerning every department of which there is so much uncertainty as in the case of Landry's paralysis. Etiology, pathological anatomy, and therapeutics are all totally blank for us, nor is there yet complete unity as to diagnosis; for symptoms have been found wanting that were considered as essential, and again other phenomena whose absence was deemed necessary to a clear diagnosis have been recorded in certain cases.

Whether Landry's paralysis, or acute myelitis of this rapidly progressive type, it seems to me, that cases in this category deserved to be ranked with infectious diseases; the infection, too, being most virulent in character, as indicated by its results. The infectious material, of unknown nature, leads to reactive changes in the spinal cord, similar to the local reaction in the lymphatic structures in typhoid fever, or in the lungs in pneumonia. This view as to etiology receives some support from the occasional association of both myelitis and Landry's paralysis with some of the exanthemata; other forms of intoxication, too, have been known to precede their development.

As between Landry's paralysis and acute myelitis it would almost seem that only the post-mortem examination of the case, from the presence or absence of recognizable alterations, will enable us to decide as to nomenclature. Now the recognition of morbid changes in the spinal cord and medulla is dependent upon very important factors, other than the existence of a lesion; I would refer especially to the methods of hardening and staining. It is my firm conviction that, in many of the cases of so-called Landry's paralysis, where no lesion could be found, inattention to the matter of hardening or staining has been the cause of obscurity in diagnosis. It may seem strange that, in this day of general familiarity with the microscope and its technology, a point of this kind should be strongly insisted upon, yet I have repeatedly seen valuable specimens ruined by ignorance or neglect of the necessary details; and in no tissue is rapid disorganization more likely to occur than in the delicately organized, unstable structure of the central nervous system.

Now, a very fair test of the success of any system of hardening is to be found in the condition of the epithelium of the central canal; where this is so well preserved that the columnar character and nuclei of the cells are visible there is little more to be asked. Such results can be uniformly obtained with the familiar Müller's fluid, provided sufficient of the fluid be employed, and the solution be changed every two weeks until the cord is transferred to alcohol. With attention to these points in the preparation, and with the selection of the proper staining reagents, the microscopic appearances of the cord will be brought out with a clearness and precision otherwise unattainable; and all the care and trouble of preparation will be fully repaid by the discovery of the anatomical changes upon which the value of the clinical history depends.

I may be permitted briefly to refer to another point of some practical assistance in the microscopic study of the cord, especially with reference to localization. All workers in this department will have recognized the difficulty, nay rather the impossibility, of deciding, in many cases, which lateral half of the cord is under examination. With all possible care in the making of sections and subsequent handling of the same, it will occasionally happen that a section is turned, so that what is really the right half of the cord comes to lie at the left of the observer.

A safe guide can always be assured by simply painting a narrow band of the outer surface, down one or other side of the entire length of the cord, with some pigment not affected by alcohol. Thus it has been my practice for some time to use for this purpose a concentrated solution of picro-carmine, which imparts its color only to the outermost layer, and stands out prominently enough against the aniline blue-black hæmatoxylin or Weigert's stain, these being the reagents that have given most satisfactory results for the finer study.

The cord, just withdrawn from the Müller's fluid, readily takes up the carmine stain, which remains through all the subsequent manipulations; and the thin band of red along the lateral columns always enables me to decide at once which lateral half of the cord is under examination. To avoid confusion, it has seemed best to always employ the carmine stain for the same lateral half of the cord, no matter what the nature of the specimen, and having begun with painting the left lateral column, I have continued to select that part as a guide, though this point is, of course, purely arbitrary.

The history of the case is as follows:

George R——, aged twenty-one; weight, 125 pounds;

English; waiter; well developed and nourished. Family history: Mother died of pneumonia; father alive and healthy; four brothers and three sisters alive and well; collateral branches negative.

November 13, 1889, 5 P.M.—Admitted to hospital; first time in hospital. Pathological history: Always been very healthy; has had measles and pertussis; denies rheumatism, malaria, typhoid fever, and pneumonia; denies ever having been affected with any venereal disease; been moderate drinker of beer for past three years. Present history: Patient states he felt perfectly well until Sunday morning (four days ago) at which time noticed that it was impossible for him to arise from his bed, owing to pain in lumbar region and both lower extremities; he also noticed that he could not easily move right leg, although motion in left was unimpaired; says he noticed nothing else until the following day, twenty-four hours later, when gradually lost all motion in right leg, also states pain in back, legs, and head, continued during this time; he walked around during first day, but was unable to do so after that; states on second day, Monday, noticed a sense of constriction about waist, he comparing it to sensation as though apron was tied about him; this pain in back he states has gradually travelled upward; complete loss of motion in right leg and impaired movement

FIG. 2.—Single Ganglion Cell from above, more highly magnified. Defines more clearly relation of lymph-space and cell, showing nucleus, nucleolus, and granular matter. 250 diameters. *Note.*—This is the centre cell or space of Fig. 1 highly magnified.

in left has continued until present time; states could move both upper extremities well until this morning, when noticed an impairment of motion in right arm, forearm, and hand, which has been gradually growing worse; states appetite has been poor and bowels constipated; says could not urinate on Monday, and took some nitre, which relieved the retention until last night, since which time has been unable to urinate. Present condition: Nervous; mental condition good, no chill or chilliness; has had vertigo at times for past three days; sleeps quite well; complains of constant pain with occasional exacerbations in both legs and back extending up to middle dorsal region; slight headache; girdle pain present. Respiratory system: No cough, no difficulty in respiration, no hæmoptysis. Circulatory system: Pulse, 108; temperature, 101.8 F. Digestive system: Appetite poor; some nausea and vomiting, which has been present for past two days; bowels constipated, no stool for past three days. Urinary system: Retention of urine, not having passed urine for twenty-four hours; urinalysis, amber, acid, specific gravity 1.030; no albumin or sugar. Physical examination: General aspect—physique good, medium height, hair dark, face somewhat flushed, expression of pain, brows corrugated, eyes normal in size and react to light. Mouth: Teeth good, tongue large, pale, flabby, coated on dorsum and not tremulous. Chest inspection: Full and well-formed, movements regular and not accelerated or limited; expansion good, no depressions present; apex-beat in normal position. Lungs: Examination negative. Heart: Action quite rapid. Abdomen: Nothing abnormal discovered with exception of tumor in hypogastric region; loaded colon. Extremities: Complete loss of motion in right leg, and movement in left is very slight; motion is also considerably affected in right arm and forearm; moves left arm readily. On testing strength with dynamometer, is found to turn index to 20 with right hand and around to 50 with left. Sensation in affected parts is unimpaired, there being a marked tendency for patient to overestimate the points touching him when using the æsthesiometer. Locates precisely part touched or irritated. Muscular sense appears somewhat diminished. Reflexes: (1) Plantar reflex present; (2) Ankle clonus absent on both sides; (3) Loss of both patellar tendon reflexes, also cremasteric and epigastric. Catheterized. Ordered antifebrin, 10 grains.

November 14th, A.M.—Pulse, 112; respiration, 28; temperature, 103.4° F. Patient slept quite well, still complains of pain in back, extending up to middle dorsal region and down both lower limbs. Pain cramp-like in character. Girdle pain present, encircling body just above umbilicus. Still unable to move right leg, but slight motion in left leg, motion in right arm more impaired. Turns index of dynamometer to 10 with right hand and to 50 with left. Respiration somewhat catching in character. Pupils normal, no appetite, no stool, vomited twice, retention of urine; catheterized. Ordered mercuric inunctions; bichl. merc. and potass. iodide by the mouth. P.M.—Complains of severe pain in head. Pulse, 104; respiration, 24; temperature, 101.6° F. Pain in back has extended up into cervical region, continuous pain in both lower limbs, with frequent exacerbations. Still unable to move right leg, motion somewhat more extensive in left leg, remains about the same in right arm but has involved left arm, motion being considerably impaired in it. Pupils contracted and react sluggishly to light; complains of seeing double; girdle sensation still present. Has pain in substernal region. Respiration very jerky in character. Anorexia present, no stool, retention of urine; catheterized. Ordered hypod. morph. sulph., ¼ grain. Ordered sherry, ℥ j.

November 15th, A.M.—Pulse, 108; respiration, 20; temperature, 102.5° F. Did not sleep well, was restless; motion in the extremities about the same as last evening; complains of pain in the back of the neck, along the spine, occipital region, and in the knees. Pupils contracted and immobile, sensation unaffected. Respiration more regular and not so jerky in character. No stool nor retention of urine; catheterized. Gave hypodermic of morphia, ¼ grain, at 2 A.M. This morning convergent strabismus present (in both eyes); turns index with left hand to 50. P.M.—Pulse, 112; respiration, 20, regular; temperature, 102° F. Cannot move either lower extremity, except moves toes of the left foot; very slight motion in the right arm; motion is much more impaired in the left arm; turns index with left hand to 15, cannot move index with the right. Sweating profusely. Respiration regular; pain in the back of the neck, back, and legs; numb sensation in arms. Pupils contracted and immobile, convergent strabismus present in both eyes. Retention of urine; catheterized; anorexia, no stools; complains of back—*i.e.*, buttocks—being sore, some congestion over same. Ordered co. jalap powd., 20 grains; morph. sulph., ¼ grain.

November 16th, A.M.—Pulse, 120; respiration, 28; temperature, 101.2° F. Patient states rested quite well and slept some during night; appears to be some slight impairment in mental faculties, as indicated by slow, hesitating speech; complains of pain in frontal region, back of the neck, along the spine, over sacrum and in the heels. Ptosis of left eyelid, partial convergent strabismus present in both eyes, but more marked in the left, pupils contracted and immobile; no paralysis of the muscles of the face; profuse perspiration over head, face,

neck, and arms; face slightly flushed; respiration accelerated and shallow; no motion in the right leg and none in the left, except is able to flex toes slightly; no movement in the right arm and is extremely slight in the left, but still able to flex fingers, as turns index to 14 this A.M.; supination of hand lost; sensation unimpaired in the extremities, localizes points touched well. Muscular sense unimpaired; temperature sense greatly impaired over the lower extremities, but retained over abdomen, chest, and upper extremities. Acute decubitus developing over sacral region, large blebs being present; no vomiting, swallows quite well, although slowly; no stool, retention of urine still present; catheterized. Ordered hypodermic morph. sulph., ¼ grain; glycerine injection into bowel. Measurements of lower limbs: Around calf, right, 12 inches; left, 11⅞ inches; around thigh, right, 16½ inches; left, 17 inches. P.M.—Pulse, 108; respiration, 24; temperature, 101.5° F. Condition unchanged since morning; heels sore; complains of pain in the stomach, elbow, calves of legs, and heels. Heels padded with cotton; lies with eyes closed; says feels better; bowels moved freely, urine retained; ate but little during the day; cannot move index with either hand to-night.

November 17th, A.M.—Pulse, 112; temperature, 100.8° F. Rested well, but did not sleep much during night. Mental condition seems somewhat affected this morning, as statements are contradictory to some that were given when came into house. Complains of pain in elbows only. Is able to move hands slightly this morning, sweating considerably, cannot turn index with either hand. Acute decubitus developed on both sacrum and heels. Strabismus and contraction of pupils still remains. Hypersensitive over affected parts; no stool, urine retained, but nurse states voided small amount. P.M.—Pulse, 108; respiration, 40; temperature, 100.8° F. Patient delirious to-night, not realizing his surroundings, wants to know which is his way home, etc., but recognizes the interne. Respiration still irregular, and somewhat catching and accelerated. Pupils contracted, and convergent strabismus still exists. Whitish secretion resembling semen exuding from penis. Moves hands and arms slightly. Still perspires freely, complains of pain in back of head and bladder.

November 18th, A.M.—Pulse, 128; respiration, 40; temperature, 101.6° F. Delirium still remains; can move forearms and flex fingers of left hand slightly, although is not able to turn index. Perspires profusely; talking to imaginary people; cannot move feet or toes; incontinence of urine. Pupils dilated by homatropia. P.M.—Pulse, 132; respiration, 36; temperature, 101.8° F. Patient still delirious; does not know where he is, talking to persons not present, etc.; recognizes interne; moves both forearms and fingers of left hand. Inspiration quick and sudden. Pupils dilated from homatropia. Sensation unimpaired, and localizes point irritated perfectly; moves toes of left foot slightly. Bed sores still remain about same. Incontinence of urine still present. Says has slight pain in back. Ophthalmoscopic examination negative.

November 19th, A.M.—Pulse, 140; respiration, 24; temperature, 105.8° F. Patient unconscious this morning, unable to speak; does not move extremities; face pallid; pupils dilated, but due to influence of homatropia. Respirations short, quick, and jerky, especially the inspiratory act. Micturition involuntary; vomiting this morning, vomited material of yellowish color. Divergent strabismus of left eye, the pupil of which is more dilated than right. 12 M.—Death quietly took place by apnœa; toward the last respirations were jerky and irregular in character.

Autopsy: Lungs, heart, spleen, liver, kidneys, stomach, intestines, and brain normal. Spinal cord—Membranes congested, but no lymph observed; cord apparently quite hard and firm; anterior horns markedly congested, being very red in color, especially in dorsal and lumbar regions.

Microscopic sections were made at eight levels of the cord, beginning at the third cervical vertebra, the lowest section being taken at the commencement of the cone that ends in the filum terminale. Some of the changes are pretty well defined in the accompanying pen-and-ink drawings, for whose careful preparation I am indebted to the skill and kindness of my friend, Dr. D. T. Vail. At all of these levels the signs of acute inflammatory reaction were plainly evident. Hemorrhages of microscopic proportion, especially into the anterior horns of the gray matter, less abundantly met with in the posterior horns, testify to the intensity of the congestion. The capillaries are everywhere mapped out as plainly as though they had been successfully injected, their calibre being distended to the utmost with red corpuscles. Around the capillaries, more decidedly, however, immediately surrounding the larger vessels, is a zone of round-celled infiltration, extending for some distance into the surrounding tissue. The perivascular and perigangliar lymph spaces are obliterated. The pia-mater and the subarachnoid spaces give equal evidence of this round-celled infiltration. There have also been destructive changes of considerable extent in the anterior horns of gray matter, increasing in intensity, and in the area involved, from above downward.

Fig. 3.

Fig. 3.—Wall of Microscopic Abscess in Right Anterior Horn, Gray Matter, Lumbar Enlargement (case here reported). Disintegration of tissue, round-celled infiltration and small capillary crowded with corpuscles (stasis). 60 diameters.

The maximum of inflammatory reaction was found in the right anterior horn of gray matter in the lumbar enlargement, where the tissue was so completely broken down that a small abscess of the size of a barley-grain had resulted. Figure 3 shows a portion of the wall of this abscess, whose fluid contents disappeared in the preparation of the sections. (The sections were all imbedded in celloidin, and no part of any section was lost either in the cutting or subsequently.) For some little distance above this level, the ganglion cells had all disappeared from the anterior horns, axis-cylinder process, nucleus and all; the places of a few cells being indicated by a granular corpuscle; for the most part the section showed a uniform round celled infiltration of the right horn, the left still retaining a few of its ganglion cells, though altered in character and surrounded by inflammatory exudation. In the dorsal region the ganglion cells are also altered in character, though few have disappeared, and it is only in the cervical enlargement and above this that we find them present in normal quantity and in character. This phrase, "altered in character," is based on their reaction with staining fluids, when contrasted with that of normal cells, as also upon indistinctness of outline, and partial or total disappearance of the nuclei. The English aniline blue-black was found most serviceable in thus discriminating between normal and altered cells. The normal ganglion cells readily take up this stain, assum-

ing a uniform bluish-black tint, with clear accentuation of the nucleus. The altered cells show a yellowish tint, which more and more completely replaces the blue color the greater the degree of cell change; this was evident from the gradual change from yellowish to blue as one proceeded from below upward. In the lumbar region the difference between the right and left halves of the cord was greater than at any of the upper levels, and in the cervical region the two sides seemed to be equally involved.

The anterior nerve-roots were, in part, included in the sections, and gave little evidence of any alteration. It is to be regretted that sections were not obtained of some of the larger peripheral nerve trunks, to determine the presence of descending degeneration, but I was unable to attend the autopsy and this point was overlooked; still the lesion in the cord was evidently the primary cause of both the motor paralysis and the trophic changes. The white matter of the cord, save for the congested condition of all its vessels, presented nothing abnormal. The Weigert stain seemed to serve best for the columns of the cord, the aniline dye for the ganglion cells and gray matter. The columns of Clarke were not involved in the inflammatory changes to any extent, other than could be explained by their contiguity to large vessels.

It would serve no purpose to enter more minutely into the microscopic appearances, as all the evidence necessary to establish the presence of an acute inflammatory condition of cord and membranes is here given, and the diagnosis of meningo-myelitis is thus plainly established.

The case had been presented to the class and lectured on as one of acute myelitis, and yet I must confess that I was not absolutely clear as to the condition that would be revealed by autopsy. I had supported my first impression by these data:

1. The presence of fever through the entire course of the disease.

2. The existence of sensory disturbance, as evident by the original pain in the back, the girdle sensation, and pains involving successively higher parts, as the disease progressed.

3. The occurrence of trophic lesions early in the course of the disease, as shown by the bed-sores over heel and sacrum.

As opposed to these were three strong clinical features that it was difficult to reconcile with the theory of an acute inflammation, and these were, firstly, the condition of complete muscular resolution presented by the patient; the absence of any convulsive movement, either tonic or clonic; the inability to obtain any clonus, and the diminished reflex responses, the reflexes soon ceasing entirely. It would be difficult to conceive a more perfect loss of muscular tone than was presented by this patient, and that, too, from the very outset.

The most profound sleep, the deepest coma, have not shown such total lack of all muscular support as was here manifested. While it was possible that a period of increased muscular irritability might have preceded the paralytic condition of the lower extremities before the patient came under observation, there was ample opportunity to study the involvement of the upper extremities from day to day; yet not at any time could we elicit an increased muscular response, nor could we detect the faintest involuntary contraction, fibrillar or otherwise. The second point to occasion doubt was the gradual progression of the disease from below upward, the progress being plainly traced with each successive observation. This conforms accurately with the recognized type of Landry's, or, as some authors choose to term it, acute ascending paralysis; and is not like the ordinary types of acute myelitis, where the damage seems to be done almost at the onset of the disease, followed by more or less improvement in a comparatively short time, as for instance, in the so-called essential paralysis of children. Thirdly, the age of the patient.

In Ziemssen's "Handbook" we find the following definition given for Landry's paralysis, from the pen of Erb. "An affection, characterized by an ascending motor paralysis, with or without febrile disturbance, usually beginning in the lower extremities, rapidly involving the trunk and upper extremities, and extending to the medulla; with these symptoms, there is little disturbance of sensibility, of the functions of the bladder and rectum, no particular atrophy of muscle, nor disturbance or diminution of electrical excitability."

Applying this to the case in hand, we find the paralysis as above, fever, little involvement of sensibility (the temperature sense alone being impaired), considerable disturbance, however, of the functions of the bladder and rectum. The electrical reaction of the muscles was, unfortunately, not tested.

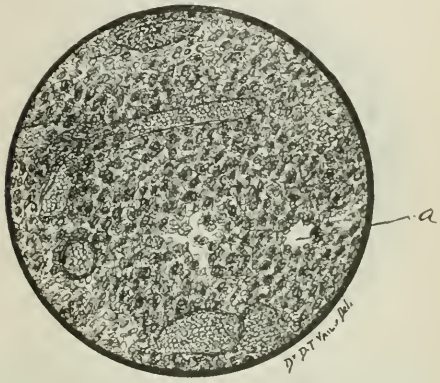

FIG. 4.—Anterior Horn, Gray Matter, Lumbar Enlargement, Left Side. Same section as Fig. 3; portion of cord corresponds to same level as Fig. 1. Total disappearance of ganglion cells, capillaries all densely packed with corpuscles, diffuse round-celled infiltration of gray matter: at *a*, free circular space, probably from destruction of a ganglion cell. 60 diameters.

A singular feature of the case, as is apparent from the history, was the integrity of the plantar reflexes, with absence of the patellar; I am unable to offer any explanation of this phenomenon. The strabismus, delirium, the ptosis, all point to an extension upward; possibly of the meningitis alone, so as to involve the nerve-trunks at the base of the brain, possibly of the inflammation of the central gray matter. Macroscopically there were no signs of basilar meningitis; the parts were not preserved for microscopic examination.

With reference to the landmarks signalled by Erb, we find very great diversity of opinion. Thus Allbutt says, where the power of the sphincters is retained, it is not true ascending paralysis. Petit, in *Gaz. Hebdom.*, 1887, says that the bladder and rectum are rarely involved, but affection of these parts is more frequent than the occurrence of bed-sores (Petit seems to be the only author who considers the possibility of trophic changes in Landry's paralysis).

Professor Schultze, of Heidelberg, in commenting upon the question of diagnosis, states that "while Landry's paralysis is generally termed 'acute ascending,' it need not necessarily follow this direction" (the well known case of Cuvier, the famous naturalist, began with dysphagia and presented a descending type); "there may or may not be disturbances of sensibility, and no one knows how much of a sensory lesion is necessary to rule the case out of the category of Landry's paralysis; fever may or may not be present; as to the condition of the reflexes, nothing positive is known, since, at the time of Landry's description, investigations of the tendon reflexes were not made. The electrical reaction is said to be normal; yet in a case of Westphal's it was absent in some muscles of the affected leg; in a case of Kahler and Pick it was generally interfered with; and as to the course

of the disease, we are equally without a guide, since it may terminate fatally or in the recovery of the patient. The most characteristic symptom is the gradual extension of the disease to the medulla, as indicated by bulbar paralysis and failure of the respiration." (According to Professor Schultze's description, our case would thus well deserve to be called a case of Landry's paralysis.)

"It need scarcely surprise us," says Professor Schultze, "if the autopsies of these cases show results equally divergent."

Westphal and Kahler found nothing abnormal in the cord; Leyden saw changes indicative of myelitis; Kümmell, in one case, observed an affection of the medulla, while Schultze himself in one case, found, as in ours, a

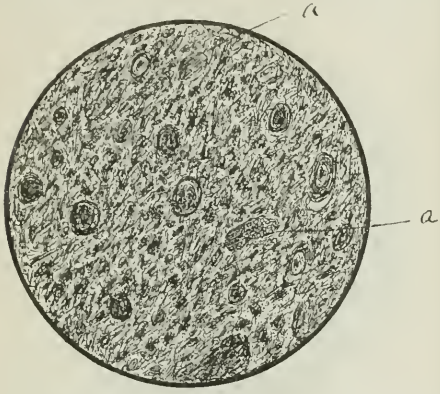

FIG. 5.—Right Anterior Horn, Gray Matter, Dorsal Cord, about Eighth Dorsal Vertebra. At *a*, ganglion cells, which have lost angular outline and nucleus, and have become very indistinct. The field is taken up largely by circular or oval granular masses, interspersed between which are round cells. The tissue presents under the microscope a general haziness, well represented in the drawing. 60 diameters.

meningo-myelitis; and it is still doubtful whether or not the peripheral nervous distribution may not contribute anatomical changes that have thus far escaped detection. For these reasons Schultze proposes, very justly we think, that the designation, Landry's paralysis, be dropped from our nosology, since the differential diagnosis between an extensive myelitis and the so-called Landry's disease cannot be made clinically; and depends altogether upon the post-mortem evidence of the presence or absence of microscopic changes. According to his suggestion, our present case would belong to the class of acute ascending motor paralyses.

Bernhardt likewise refers to the difficulty of diagnosis *intra vitam*, and shows that disturbances of sensibility may or may not be present, that there may be polio-myelitis anterior of mild intensity with preservation of normal electrical irritability, and that, per contra, with disseminated lesions of the antero-lateral columns, without much involvement of the gray matter, the electrical reaction is frequently lost. Schwarze reports a case ending in recovery, with absence of the reflexes, dysphagia, pain, and changes in electrical reaction, which he yet terms Landry's paralysis. I have been at some pains to trace the reaction as to reflexes, and have found it very inconstant. In our case, with persistence of the superficial plantar reflex, the deep patellar was wanting. In a case reported by Jaffé all the reflexes were lost, as also in the case of Schwarz and one reported by Hoffmann, while in the case of Rumff there was no affection of the tendon reflexes, while the plantar reflex was absent.

It may seem like useless reiteration of a point already well established to show that, as to sensory disturbances, there is the same uncertainty. An examination of the literature would seem to show that such perversions of sensibility may occur as preliminary to other symptoms, or during the disease, or may be wholly wanting. To quote merely from a few cases: in a patient of Mieth, there was a feeling as if the hands were washed in sand; in the case of Rumff there was acute sensory disturbance, both of muscle and of the skin; in Hoffmann's patient there was a feeling of great fatigue for some time preceding the attack, which was attended, at the onset, by formication in the thighs; in one case reported by Westphal there was numbness in the affected part; and in a case of P. Lévi's there were for two or three weeks, fatigue, prostration, and heaviness in the head, and formication in the toes.

With a clinical history as above detailed there is much to hold our interest in the question of pathology. What can be the nature of an affection which, selecting its subjects from the most vigorous period of adult life, between the ages of twenty and forty, seizes upon them without premonition, and quickly renders the strong man prostrate, more feeble and more helpless than the new-born babe; adding, if possible, to the misery of his situation by leaving him the consciousness of his own impotence, and, oft-times, of the irremediable nature of his malady? Surely, there is something in the mode of its onset that forcibly recalls the infectious poisons; how else can we explain the fatal issue that follows so briefly upon the development of the earliest symptom? Thus Pitres and Vaillard narrate a history of death within fifteen hours; Van d. Velden has described one case in which death took place thirty-six hours after the beginning of the attack; another is reported in the *London Lancet*, terminating in death on the third day, where the patient was at work three days before her demise. This analogy with the acute infectious processes had impressed many of the earlier observers; and attention has been called to the association of this form of paralysis with typhoid fever, malarial intoxication, variola, and influenza, and to the resemblance of many of its features with diphtheritic and alcoholic paralysis.

This last clinical fact led, naturally enough, to the search for peripheral nervous lesions, such as constitute

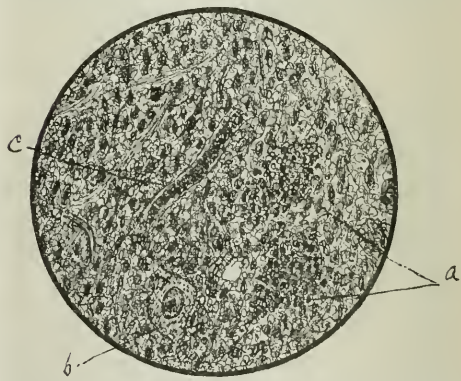

FIG. 6.—Anterior Horn (Right), Cervical Enlargement. Capillary congestion still evident. At *a* hemorrhages into gray matter; at *b*, ganglion cell, showing normal outline, nucleus, and nucleolus, but total obliteration of pericellular lymph space. Some round-celled infiltration also evident at this level of the cord. At *c*, injected capillary vessel. 60 diameters.

the anatomical basis for alcoholic neuritis; such lesions, too, have been found in acute ascending paralysis. Oppenheim has but recently called attention to this fact; Pitres and Vaillard earlier, expressed the opinion that the lesions were the same as in alcoholic paralysis, and Petit favors the view that it is a general peripheral neuritis of toxic origin. Hoffmann has found lesions not only of the gray matter, but swelling of the axis cylinders in the anterior and lateral columns and in the intra-medullary portion of the anterior roots.

Déjérine concludes that we are dealing with alterations in the anterior roots and peripheral nerves, like the changes observed after division of a nerve, the so-called "trau-

matic degeneration"; and Van d. Velden, who also noted swelling of the axis-cylinders and changes in the nerve-fibres, attributes these changes in the myeline to some infectious agent.

All authors seem agreed as to the infectious nature of the process; yet the search for an organized virus, or producer of a virus, has not succeeded in giving us a pathogenic bacterium or coccus; and yet it seems to us most likely that the solution of the etiology is to be found in this direction. It is but a short time since that the problem of the pathology of tetanus, whose anatomical substratum was far more vague and indistinct, has been satisfactorily settled by the discoveries of Brieger; and it is fair to infer that a similar success will attend studies in this direction, with reference to acute ascending paralysis.

Our own conclusions, based upon the investigation of this one case, and a careful study of the literature of the subject are:

1. The term "Landry's paralysis," as being wholly unscientific, should be dropped entirely, and the name "Acute progressive motor paralysis" substituted.

2. That by this term we understand an acute infectious process, a pathological entity, whose virus expends its effects primarily upon the gray matter of the anterior horns of the cord.

3. That, as in other intoxications, the economy may be so prostrated by the poison that time is hardly given for the anatomical changes characteristic of the affection, before the patient succumbs; hence, the inability to find notable lesions in cases of very short duration.

4. That, in cases of longer duration, lesions characteristic of inflammation of the gray matter and of the cord can generally be met with, in the form of inflammatory stasis, perivascular infiltration, microscopic hemorrhages, swelling of the ganglion cells, of the axis-cylinders, and destruction of ganglion cells; the intensity of the lesion usually being greatest at the point first involved; *i.e.*, the lumbar part of the cord. It is, however, to be borne in mind that, as in the case of diphtheria, the local manifestation is not necessarily initiated at any one part; so that we may have exceptional instances in which the process begins above and extends successively to lower levels.

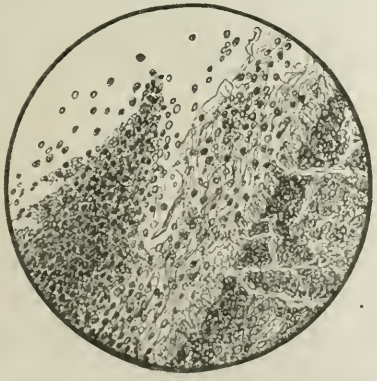

FIG. 7.—Shows Participation of Meninges in Inflammatory Process. Taken from same specimen as No. 6 in neighborhood of posterior root. Swelling of membrane, separation of fibres, round-celled infiltration, with a considerable hemorrhage at left of the field. 60 diameters.

5. That, secondary to changes, anatomical or molecular, in the ganglion cells of the anterior horns of gray matter in the cord, or their congeners in the medulla, lesions are found in the peripheral motor nerves, comparable to those which follow the separation of every nerve fibre from its ganglionic connection; and these lesions are to be ascribed to disturbances of nutrition of the ganglion cell itself.

Such state of impaired nutrition may be but transitory, leaving the ganglion cell in condition easily to recover; and yet, may cause more gradual and more lasting disturbance in the nerves coming from the cells. This would explain the pathological anatomy of cases in which the cord has been found healthy and the peripheral nerves have shown decided alterations.

6. That, while sensory disturbances are not the rule, they occur too frequently to be considered exceptional, and are probably due to the altered condition of circulation in the cord, incidental to the inflammation of the anterior horns, or may be ascribed to an extension of the inflammation in the gray matter to the posterior commissure or posterior horns, by mere contiguity of tissue. (At some levels minute hemorrhages were found in the posterior horn. They were always small in extent, and not surrounded by

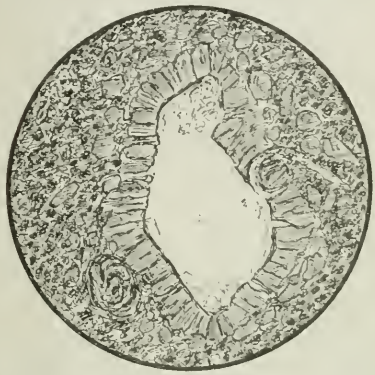

FIG. 8.—Central Canal, Dorsal Region. Same section as Fig. 5, as shown to prove that the indistinct outlines in gray matter are due to disease, and not to defective hardening. Cylindrical character of epithelium and individual cells clearly shown. 160 diameters.

the signs of active inflammation, as in the anterior horns of the same section.)

7. That a meningitis confined to the pia, and not of sufficient intensity to lead to plastic effusion, frequently accompanies the process in the cord.

8. That the affection is commonly fatal, but not necessarily so, and it is wrong to make the diagnosis contingent upon the fatal issue. When death occurs, it has been found in nearly every instance to depend upon embarrassment and final failure of the respiration, occasioned by the extension of the process to the ganglion cells directly concerned in the innervation of the muscles of respiration; especial importance being naturally attached to the cells giving off the root-fibres of the phrenic nerve.

9. That the absence of trophic lesions in the majority of cases is to be explained by the rapid course of the more severe cases, or by the fact, that an attack of milder severity does not lead to extensive destruction of ganglion cells. Trophic lesions may occur, as above conclusively shown by our own case.

10. That age, in a measure, seems to be a predisposing factor, the two decades between twenty and forty showing the largest number of cases; children and old people have, however, furnished some examples.

11. There seems to be no connection, as far as known, between this affection and any previous syphilitic infection.

12. The closest analogy exists between this affection and acute polio-myelitis of children; the difference in results is susceptible of ready explanation. In the myelitis of children the intensity of the poison is expended in a very limited area, from which cause there result complete destruction of ganglion cells, with subsequent paralytic and trophic symptoms, that are liable to be lasting through life. In acute progressive motor paralysis the affection invades the entire cord, and, consequently, is less apt to produce destructive changes in cases of mild in-

tensity; so that, when recovery occurs, we see little of its effects subsequently. In the more severe cases, from the tendency to involve centres of respiration, the permanent nutritive and paralytic symptoms are anticipated by the death of the patient.

CRANIECTOMY FOR MICROCEPHALUS.

By JOHN A. WYETH, M.D.,

PROFESSOR OF SURGERY, NEW YORK POLYCLINIC; SURGEON TO MOUNT SINAI HOSPITAL.

CASE.—Male child born at term, February 2, 1890, normal labor, without deformity, weighed nearly six pounds. First child of parents about twenty-five years of age, both healthy and of normal development. The mother noticed that when her baby was four weeks old the throbbing in the anterior fontanelle ceased. Beyond this nothing unusual was observed until the third month, when the child had whooping-cough, and became very nervous, screaming as if in pain, and extremely wakeful. The attending physician informed the mother that the "soft spot" on top of the head had closed by ossification, and that the trouble was due to compression of the brain. In July morphia and chloral were given to secure sleep, and this was continued for some months. September 27th, at 11.30 A.M., he was seized with a cataleptic attack, and remained motionless and "as if dead" until 1 P.M. Following this attack the feet were drawn inward (talipes equino-varus), the left foot most affected, the left hand was also slightly flexed.

By November 21st he had improved so much that the opiates were discontinued, and the child immediately began to take on flesh and grow. The cranium, however, did not expand. January 1, 1891, he came under my care, through the courtesy of Dr. T. S. Galbraith. At this time he presented the appearance of a fairly nourished child of eleven months. The face was fat and rosy, the cheeks fat, and the face well developed. The cranium was small, about as large as that of an ordinary two-months-old infant, and sharp-pointed. The eyes moved convulsively at times, pupils dilated, did not seem to appreciate objects, and had a dull look, as if indifferent to everything around it. The hands and arms did not move co-ordinately to grasp proffered objects, but were chiefly engaged in jerky movements toward the mouth. When the thumb by one of these manœuvres slipped into the mouth it would remain there, and he would suck at it for a while, until by a spasmodic movement it was displaced, when the effort to replace it would be renewed. The chest and abdomen, genitals and thighs, were to all appearances normal and of full development. Legs somewhat small, and talipes equino-varus on both sides, less marked on right.

Encouraged by the report of Lannelongue's case, a notice of which only I had seen in an editorial in the MEDICAL RECORD, I advised operation, and on January 7, 1891, carried out the following procedure:

Chloroform; head shaved; antiseptic details. Incision in median line from near base of nose to just beyond occipital protuberance. Pericranium pulled aside to expose skull for about one inch on either side of median line; cranial bones firmly ossified. No interosseous cartilage observed. Small trephine applied, and two long trenches made with rongeur, one-quarter inch wide, and extending from just above the eyes to the occipital protuberance, leaving a bridge three-fourths of an inch wide to protect the superior longitudinal sinus in its entire length. I then, at either end of these two trenches, cut out laterally one inch, and with bone scissors divided the parietal bones for one inch and a half in the middle of the top of the head, cutting perpendicularly in the direction of either ear. I now inserted my four fingers beneath each half of the exposed skull bones and tore these loose from the dura mater, raising them freely and thus widening the trenches to one inch each. The dura was not opened. Catgut ligatures. Catgut soft wisps inserted for drainage on either side from front to back, between skull and dura. Irrigation with 1 to 5,000 bichloride. Pericranium stitched in middle line with catgut. Aseptic dressing. Patient sank under the chloroform early in operation, and the anæsthetic was discontinued; completed without narcosis. Time, one hour and thirty minutes. Rallied well. By January 10th some improvement in intelligence was noticed. On the eighth day it was very evident. The child noticed those about it, and the eyes followed moving objects. It would grasp the hand when offered, and slept without narcotics. Ate fairly well. Wound dressed on tenth day, and united by first intention without suppuration.

Patient left the city for its home on sixteenth day after operation. The inversion of the feet is much less noticeable, and the jerky movements of the hands are no longer so well marked. In a letter just received the mother writes: "The baby is much improved. He notices everything just as all babies do. I can notice such a change in him."

I saw the child one month after the operation and the change in its condition was surprising and gratifying. The deformities in the extremities had entirely disappeared and there was evidently a remarkable increase in intelligence. It noticed those about it, took hold of objects offered it, laughed, and behaved much as children of ordinary development at six or eight months. The pupils were no longer widely dilated but appeared normal. It eats and sleeps well and is in general greatly improved as a result of the operation.

The operation differs from any yet done. Lannelongue, Keen, and others cut a trench about a quarter of an inch in width, and on one side, at a single operation. It seemed to me if the brain was penned in by premature ossification of the cranial bones, these should be torn loose and permanently lifted, thus allowing a thorough expansion. Should only temporary benefit be secured, the operation should be repeated. Experience alone can demonstrate whether the expansion of the brain will be able to spread the cranial bones to such an extent that it may reach even an ordinary development. The condition of these patients is so hopeless and deplorable that, in my opinion, very great risk is justifiable in any surgical interference which offers even a hope of amelioration.

AN ABDOMINAL TUMOR IN A MALE.

By CHARLES E. WOODRUFF, M.D.,

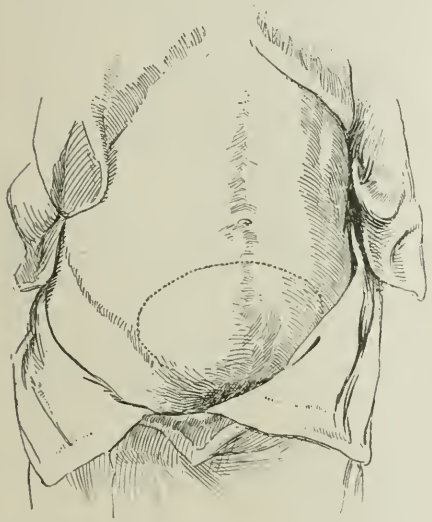
ASSISTANT SURGEON, U. S. ARMY, FORT GASTON, CAL.

ON September 14, 1890, T. G——, aged fifty-nine, miner by profession, presented himself with the following history: Until five weeks ago he had been perfectly well, with the exception of frequent micturition, which dates back several years and which is probably due to an uniformly enlarged prostate. He has been a drinking man, has had occasional sprees for the last thirty years, and now presents an aged appearance beyond his years, common to men of his habits. He has always been gaunt in appearance, though muscular. His abdomen has never protruded, but, on the contrary, has usually been retracted as in men of his build. About five weeks ago he went to bed perfectly well, but was wakened by a chill which persisted until morning. On rising he noticed a slight swelling in the right side of the hypogastric region, about the size of his fist. The swelling gradually enlarged, until in thirty-six hours more it reached almost to the sternum. It was not painful, except to a slight extent on pressure, but gave a feeling of uneasiness, which was relieved by lying on his back with his thighs drawn up toward his abdomen. The uneasiness was more marked at night than during the day, and exists at present only slightly toward evening. He has always slept well, and has not been confined to his bed a single day. When the swelling was at its greatest there was some vomiting, which per-

sisted two or three days, and was followed by a diarrhœa lasting two days, with dark, offensive stools. During this period he also noticed that he could not inflate his lungs with the usual degree of satisfaction, but had the feeling as though he could not get enough air, though no actual dyspnœa ever appeared. At the present time he occasionally takes a long, deep, sighing respiration, as though the act were still interfered with.

After a few days the swelling began to subside slowly but continuously, until at present it is of the appearance shown in the accompanying photograph. The swelling has always extended more to the right side.

Owing to lack of appetite, he became thinner than usual and somewhat weakened, but as soon as some strength returned he began his forty-five mile walk over rough mountain trails to see the doctor. He made but little distance during the first few days, but noticed that his appetite at once began to increase, and now, at the end of the fifth day, he eats well, sleeps well, and beyond the



uneasiness at the lower part of the abdomen he feels as well as ever.

A thorough examination reveals the following conditions: The lungs are normal throughout. The heart presents one peculiarity, namely, a well-marked double first sound, but in all other respects nothing abnormal can be detected. The liver dulness is but one-half of what it should be. There is no ascites. The splenic dulness is normal. In the abdomen there is an area of flatness in the hypogastric, umbilical, and right inguinal regions, corresponding in outline to the ink mark on the abdomen, as shown in the photograph, which also shows the protruding condition of the abdomen. This area is about seven inches long and six wide, the long axis extending obliquely downward and to the right, into the right inguinal region. On palpating, a slight pulsation can be detected, most probably being due to the transmitted pulsation from the abdominal aorta and iliacs. The area of flatness corresponds to a tumor with smooth surface, giving fairly well-marked fluctuation and movable transversely to an extent of about an inch and a half. Auscultation reveals nothing whatever. Posteriorly the area of flatness over the left kidney is slightly increased, but over the region of the right kidney, instead of flatness on percussion, there is a dull resonance over part of the area, and a tympanitic sound over the rest. The urine is in fair quantity, absolute measurement unknown, no albumin, no casts. The bladder contained about one ounce of urine at the time of the examination, and this was drawn off by a catheter.

The diagnosis of this interesting case was at first in great doubt, but on the supposition that the patient had a floating kidney a fairly good diagnosis may be made. The above supposition is not too much to assume considering the facts that the right kidney, if one exists, is not now in its proper place, that the tumor has always tended toward the right side, and that the floating kidney usually is from the right side and may exist for years without symptoms. The cause of the rapid increase in size of the kidney, assuming that the tumor really is the right kidney, presents further difficulty. Hydronephrosis may have existed in the right kidney for a long time without symptoms, as is usually found to be the case in this disease. The movements of a floating kidney must give numerous opportunities for compression or twisting of the ureter, thus obstructing the flow of urine and giving rise to hydronephrosis. The diagnosis of hydronephrosis in a floating kidney, or rather displaced kidney, seems to fit the case fairly well, except for the enormous and sudden increase in size which occurred five weeks ago, yet even this fact may be in favor of the diagnosis. It is by no means certain that the kidney did enlarge so rapidly as it appeared to. It may have been enlarging for a long time and have been quite large five weeks ago, without the patient's knowledge. Suddenly settling itself in the lower part of the abdomen it may have given the appearance of having arisen during the night. Again, it is not certain that the tumor did enlarge so as to reach nearly to the sternum. A feeling of distention and a displacement of the intestines upward may have given the feeling to the patient that the tumor had really extended that far. The increase and then diminution in the size of the tumor really supports the diagnosis of hydronephrosis, for such a course is not unusual in cases of this affection. The apparent enlargement of the left kidney points to the fact that the right kidney is disabled. The differential diagnosis between hydronephrosis and hydatid cyst of the kidney is impossible in many cases; but in this case it is reasonable to exclude hydatid, from the fact that the diminution in the tumor was not accompanied by anything abnormal in the urine, and the further fact that the bowel affection seemed to have had no effect upon the size of the tumor. The movements of the bowels have been normal in frequency and appearance since the slight attack of diarrhœa, and there is no certainty that contents of an hydatid cyst have escaped by any channel. The only tumor which is usually confounded with either hydronephrosis or hydatid is ovarian cyst, which of course does not enter into this case. The entire absence of any marked illness or fever excludes inflammatory affections, and it is hardly possible that an aneurism now full of fibrin could have enlarged to so great an extent without producing prostration. Indeed the rapidity of the increase in size seems to exclude aneurism.

Should we, then, be dealing with hydronephrosis, we have a rare combination, for I can find but one reference to the possibility of hydronephrosis occurring in a floating or displaced kidney. The case is still more interesting from the fact that both diseases or conditions are generally found in women, their appearance in men being the exception to the rule.

Indican in the Urine of Children.—According to Dr. Hochsinger, indican is usually not present during the period of lactation, but a trace of this substance is found in children artificially fed. In breast-fed children indican is entirely absent. Simple dyspepsia and diarrhœa and also habitual constipation in nursing children and young children do not produce this body in the urine. Cholera infantum and chronic diarrhœa result in its formation. When primary intestinal lesions and septic infection are excluded a considerable amount of indican points to the presence of tubercular disease. Children older than nurslings show the same reaction to tests for indican as adults.—*Wiener medicinische Presse.*

Progress of Medical Science.

The Diagnosis of Pulmonary Cavities in Children.—Dr. Aldibert calls attention to the untrustworthy character of the physical signs of pulmonary cavities in children. Dulness, cavernous breathing, gurgling, and the cracked-pot sound may all be present in cases not only of pleurisy, acute and subacute, but also in acute pneumonia. On the other hand, the most careful auscultation and percussion may fail to discover any signs of even large cavities proved to have existed by post-mortem examination. He also points out that the localization of physical signs at the apices is not, in children, evidence of their tubercular nature. Several well-observed cases are recorded, and his conclusion is that the signs of pulmonary cavities in children must be interpreted with the greatest reserve.—*Revue des Maladies de l'Enfance.*

Gonorrhœal Salpingitis. — Dr. Terillon states that gonorrhœal salpingitis presents three modes of invasion: 1. Acute vaginitis, followed by endometritis, and finally by salpingitis. 2. Mild vaginitis, sudden development of pelvic peritonitis, the early symptoms of salpingitis. 3. Absence of vaginitis, uterine and tubal gonorrhœa. The first two varieties are due to infection with the virus of an active gonorrhœa; the third variety to the virus of an old or latent gonorrhœa. Salpingitis, according to the statistics of Fournier, occurs in one-fifth of all cases of gonorrhœa in the female. When the disease is limited to the mucous membrane of the tubes, and but little pus is formed, the prognosis is favorable. At the menopause all symptoms generally disappear. It must be remembered, however, that even in this relatively benign form life may be endangered at any moment by the sudden development of peritonitis. But suppuration with encystment is more frequent than this simple catarrh. The pus sac may rupture either into the uterus or into the rectum, or, far more frequently, into the peritoneum, provoking a fatal peritonitis. A similar peritonitis may develop before any accumulation of pus in the tubes, from mere extension. In non-encysted cases a small quantity of pus may escape from the tube, producing a local peritonitis with the formation of false membranes, which constitute a protective envelope. This may rupture at some point with a similar result, and so on, even fifteen or twenty times, as Terillon has observed, constituting a relapsing peritonitis. Gonorrhœal salpingitis is nearly always double, and consequently entails sterility.

The treatment of salpingitis is both medical and surgical. Of curetting it may be said, that if justified by the endometritis, it has no influence on the tubes. Medical treatment is wholly symptomatic. Rest in bed, with hot-water vaginal irrigations for pain; revulsives, either blisters or punctate cauterization, possess marked resolvent power. Constipation, which always accompanies the disease, should be relieved, and peritonitis should be combated with appropriate measures. These means may alleviate or even cure the peritonitis, but they cannot eradicate the basic disease, which may, at any moment, unexpectedly assume an alarming form.—*Bulletin Médical.*

Massage in Fractures.—Dr. Crickx, of Brussels, advocates the treatment of fractures by massage instead of by plaster-of-Paris bandages. Although massage has been practised successfully in such fractures as those of the humerus and tibia, it is especially suitable for fractures of the fibula and radius. He commences by effleurage with centripetal movements, avoiding for the first few days the seat of the fracture itself. An increase of pain sometimes occurs, but should not alarm the surgeon or induce him to desist from the treatment. After a short time the movements are increased in force. After about ten days pétrissage of the muscles may be commenced. All this time the limb is kept without a splint, or simply laid in a hollow back splint of pasteboard. The massage is continued until the cure is complete. In addition to the cases mentioned above, massage may be usefully adopted in fractures of the patella, olecranon, and of processes such as the epitrochlear and the styloid. Dr. Lebrun also reports several cases of fracture in which massage was employed by himself or by his house-surgeon with considerable success. In one of these, where a man had missed his footing in attempting to get on a car, and had sustained a fracture of the fibula, together with a sprain and effusion of blood under the skin, the leg was first put up in a starch bandage, but was so painful that after a few hours this was taken off, and massage practised, which afforded immense relief.—*La Clinique.*

Trephining the Spine.—From a painstaking study of this question Dr. Chipault has announced the following conclusions: 1. Trephining is useless when after the cord is contused the displaced fragments fall back on to their normal position. 2. Trephining is certainly of use (*a*) when the cord is pressed between the body and the posterior arch; (*b*) when the cord is compressed by blood clots. Under these two conditions no time should be lost, since secondary degeneration sets in very rapidly. 3. Trephining is absolutely indicated (*a*) when the spinal symptoms are due to compression of the cord by fragments posterior to it; (*b*) when there is a compression of the cauda equina, whatever its cause may be. operate at the end of some months after the condition has remained stationary for some time.—*Gazette des Hôpitaux.*

Siphon Drainage in Empyema.—Dr. Bülau advocates siphon drainage in preference to simple incision, or the resection of ribs in the treatment of empyema. Siphonage has got into disrepute with certain authorities, not because of its own defects, but because it has not been properly applied. Several cases are quoted to show the kind of results that may be obtained by means of siphonage if used carefully, one of which illustrates two facts of considerable importance. It proves conclusively that the lessening of the pressure within the pleura is an active factor in the re-expansion of the lung, and also that a lung is still capable of being thus re-expanded after having been subjected to pressure and consequent inactivity for a period of fifteen months. The application of siphonage after the chest has already been opened and drained by simple incision is also proved to have been successful in aiding the re-expansion of the compressed lung. He advises that the skin should be nicked with a scalpel before the introduction of the trocar, and that a tube should be passed in through the cannula, the latter being withdrawn over it. The tube being then firmly secured to the side and sealed to prevent the entry of air, the slow escape of the fluid through a siphon attached to the tube is followed by a corresponding expansion of the lung. This result is, of course, modified by the adhesive and other changes that may have taken place in the pleural layers, but it is claimed that in such cases expansion is equally impossible under all forms of treatment. The possible blocking of the tube by coagulating fibrin, etc., is not regarded as a serious defect in this system of drainage, as it can generally be got over without difficulty. Nor is the nipping of the tube by the ribs or healing tissue a matter of importance. When re-expansion has taken place to a considerable extent the siphon arrangement may be discontinued and a short tube left in, guarded at its orifice with a valvular covering of gold-beaters' skin, to permit the exit of fluid but not the entry of air. As a general guiding principle of treatment, Dr. Bülau maintains that if the same result can be got by simple means, such as siphonage, the more serious measure of resection of ribs cannot be justified.—*Zeitschrift für klinische Medicin.*

The Medico-legal Value of the Gonococcus.—Professor J. Kratter describes some cases of vulvo-vaginitis in girls where a positive diagnosis was only made after finding the micro-organisms in the discharges. He concludes

as follows: 1. The decision whether or not a vaginal discharge (after rape) is traumatic or infectious can only be arrived at after a bacteriological examination. 2. The detection of gonococci in such a discharge is proof positive of the presence of gonorrhœa, which has probably been conveyed in the sexual act. 3. The negative result of such an examination does not justify one in absolutely excluding gonorrhœa, as there are cases of undoubted gonorrhœa in which few gonococci are found, and only after repeated examinations.—*Berliner klinische Wochenschrift.*

The Preventive Treatment of Sympathetic Ophthalmia.—Sympathetic ophthalmia includes the different pathological conditions which may arise in a healthy eye, in consequence of changes in the other eye arising from a traumatic or spontaneous cause. Dr. Rolland gives the following spontaneous causes: Irido-choroiditis, anterior synechiæ, staphylomata, tumors, and ossification of the choroid, tuberculosis of the iris, panophthalmitis without external wound, dislocations of the lens, glaucoma, hydrophthalmia, detachment of the retina, entropion, symblepharon, cysticercus, and herpes zoster. Although the author makes no distinction in the mode of production of sympathetic neurosis and inflammation, he evidently considers the first as an early stage of the second; therefore conditions which cause the first must, according to him, be capable of causing the second. He holds that transmission to the second eye may take place along any of the various channels that have been suggested, and the cases probably differ in this respect, that as there are no means of telling in a given case which is the conducting channel, enucleation, which interrupts them all, is the only safeguard. The following are his conclusions: 1, When an eye, lost from any cause, is the seat of continuous or intermittent tenderness, or is in a condition of acute or chronic inflammation, it may give rise to sympathetic affection of the other eye, and enucleation is called for; 2, enucleation should be had recourse to on the earliest appearance of sympathetic symptoms; when irido cho roiditis, with exudation, has already occurred it is seldom effectual; 3, when an eye has been destroyed by an injury, immediate enucleation should be performed, the patient being thus protected from the pain of the inflammation in the injured eye, and from all risk of sympathetic affection of the sound eye.—*Recueil d'Ophthalmologie.*

Creolin in Erysipelas and Eczema.—Dr. Rothe has used in the treatment of erysipelas a creolin ointment containing creolin, 1.5; cret. præp., axung. porc., āā 15.0; ol. menth. pip., gtt. v. This is spread in the thickness of the blade of a knife over the diseased parts twice or three times a day, a thin layer of cotton wool being applied as a covering. In from twelve to twenty-four hours improvement was always apparent, and the disease was cured in three or four days. The same ointment also did good service in a case of weeping eczema of the face, as also in several cases of eczema in children. A patient suffering from scabies was treated with a thorough washing with soft soap and inunction of this ointment, with such a decided effect that Dr. Rothe considers creolin to be undoubtedly a specific for the disease.—*Memorabilien.*

Notes on the Radical Cure of Hernia.—Statistical notes of cases of hernia treated by Billroth, are published by Dr. Haidenthaler. They comprise 136 cases of inguinal, femoral, and umbilical rupture in both sexes. In 93 cases an operation had been performed, while in five instances the patients were treated by injecting alcohol into the sac. The operation employed was Czerny's, and consisted in ligaturing and removing the neck of the sac, and uniting the deep and superficial parts of the wound with silk sutures. The mortality in the non-strangulated cases was between six and seven per cent., and the causes of death when it occurred were entirely of septic origin. As to the final results, they were mostly true cases of radical cure, though occasionally the herniæ returned, in one instance six years after the first operation, and in three cases after a lapse of five years. The cases of alcoholic injection of the sac seemed at first to yield excellent results, but they were not permanent. The surgeons owed a great deal of the success of their operations to the thickness of the silk ligatures. The stouter ones seemed to hold the edges of the wound longer in apposition, hence the success which it seems to yield.—*Centralblatt für Chirurgie.*

Electro-puncture in Chronic Hydrocele.—According to Dr. W. Zuelzer this method of treatment, from which so much has been expected, has gradually lost ground, owing to the fact that recurrences took place in the vast majority of cases in which it was employed. Among the author's cases permanent recovery was observed in only one instance, although the application was made twice. He thinks, however, that the method is applicable in cases where the patient is so greatly debilitated that irritant injections or the radical operation are contra indicated. Electro-puncture is preferable to simple puncture, in that it is free from any ill effects; and this is due to the fact that the absorption of hydrocele fluid takes place slowly and gradually. The author employs two platinum needles, which are coated with an insulating layer up to the point. Both are inserted, as far apart as possible, into the sac of the hydrocele, connected with a constant battery; a current having a strength of three, or at the most four, milliampères is passed through them. The sittings should not exceed two to two and a half minutes. During the application active vermicular contractions of the scrotum are observed. The pain is inconsiderable if the current is not passed through for too long a period. In many cases after the removal of the needles, and careful closure of the punctures, a gradual diminution in the size of the tumor ensued. Occasionally œdema of the scrotum occurred during the first few hours, which rapidly disappeared. Within eight days the fluid has been entirely absorbed, and by the employment of proper bandages and a snugly fitting suspensory its reaccumulation can be prevented for a long time—in some of Zuelzer's cases for as long as six months. One of the advantages of the method is the rapidity with which it excites absorption, the quantity of urine being materially increased during the first twenty-four hours after the operation. In all the cases the inner surface of the sac was found covered with coagula as early as the first day, so as to be no longer transparent, and even when the fluid reaccumulated the characteristic translucency was never as marked as before.—*Journal of Cutaneous and Genito urinary Diseases.*

Myxœdema Relieved by Thyroid Grafting.—The disappearance of the thyroid body is a common feature in all cases of myxœdema. The removal of the thyroid produces in animals conditions analogous to those of myxœdema in the human being, while the trials of grafting the thyroid has so far succeeded in animals as to warrant its trial in man. M. Walther undertook grafting in a recent case. The patient was almost a dwarf (height about four feet), but with perfect intelligence. Myxœdema appeared at the age of thirty years, having been preceded during the previous ten years by frequent uterine hemorrhage. She was also subject to epistaxis and bleeding from the gums. When these hemorrhages occurred the symptoms of the myxœdema increased. The patient was received on account of the uterine hemorrhages, which resisted ordinary treatment. M. Walther grafted a portion of a sheep's thyroid in the submammary region. The wound healed by first intention. Three days subsequently the hemorrhage ceased, and had not recurred. Improvement of the general health followed. From these facts it would appear that the thyroid body performs an important part in blood-making. In this case there was an increase of red globules. The quantity of urea in the urine also became increased. Briefly, the patient recovered health. The grafted thyroid disappeared, probably by simple atrophy.—*Le Progrès Médical.*

MEDICAL • RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, February 21, 1891.

NEW YORK CITY CHARITIES.

THE fourth edition of the directory published by the Charity Organization Society, suggests some thoughts on the general subject of charitable aid, and especially that form of it pertaining to medical treatment. From the valuable index of the volume we discover that there are under the heading of asylums thirty-seven entries; dispensaries, sixty-two; homes, one hundred and seventeen; and hospitals, seventy-three. There are in all these lists the names of institutions of which we have never even heard, much less known anything about. Yet although they are mentioned in this particular volume we need not necessarily admit their claim to recognition as worthy of support. There are, as is noted in our reviewing column, organizations for supplying everything from beef-tea to moral aid.

The work of the Charity Organization Society has always found a defender in the columns of the RECORD. We have always believed, and still do, that along the lines of its efforts lies the true solution of the problem of aid to the sick. This question will never be settled until it is settled rightly, and the first step toward such a settlement must be the determination of who are worthy and who are unworthy of such aid. This distinction the Society endeavors to make, and its work has been carried to such a degree of perfection that the career of the professional mendicant who is able to care for himself is generally brief and his end inglorious.

The title page of the volume bears the motto, "United, an army; divided, a mob." This naturally suggests the inquiry, Are our institutions as an aggregate under any discipline in their relations to the public, or are they under mob rule? We are glad to believe that the former is true. It is also true that certain classes of our institutions, notably some of the dispensaries, suggest a mob in their eager rush after patients in order to make out a large number treated, and to produce a corresponding pride in the managerial bosom, but this exception only proves the rule.

We note in the preface of the book these words: "Societies and institutions have necessarily been included of whose utility and wise management grave doubts are entertained by some persons," and "the omission of any society from this volume does not necessarily discredit it," but it is believed that every worthy organization receives mention unless it has been organized since the book went to press.

Will not some of our public-spirited citizens place the Society on a sounder financial footing? It is greatly hampered in its works by a lack of funds. It does not ask for the privilege of distributing the money of the charitable; but it simply aims to prevent them from being imposed upon. And so full is the information that it freely gives that no one who finds himself victimized has any excuse.

MEDICAL EDUCATION.

THE advancement of the standard of medical education has developed into a movement which has caught the attention of the better part of the entire profession. Very small and puny it was when in 1868 the Chicago Medical College started the ball rolling by adopting a three years graded course of study. Slowly but surely, however, the movement grew in popularity. Numerous States founded boards of examiners, and several organizations were established whose aim was to advance medical education and suppress fraudulent practitioners. Within the past ten years the advance has been rapid, as will be seen by the following figures: In 1882 only 45 colleges in the United States and Canada required educational qualifications for matriculation; now the number is 129. Of 148 medical colleges, 123 now teach hygiene and 119 teach medical jurisprudence. In 1882 these branches were taught in 52 and 61 colleges respectively. In 1862 and 1863 the average length of the lecture terms was 23.5 weeks; the average is now 26.3 weeks. There are now 111 colleges that have lecture terms of six months or more, while in 1882–83 the number was 42.

In some of the largest universities in this country courses preliminary to the study of medicine are offered—the University of Pennsylvania, Cornell, Yale, Princeton, Lake Forest, and Northwestern universities. Johns Hopkins, and the University of Wisconsin; while Harvard and Columbia have made arrangements by which those intending to study medicine can take a special A.B. course in three years. The movement for four years' study of medicine and three courses of lectures is an assured success. During the past year the list of colleges that now require or will require within one or two years more courses and time of study has grown considerably. There are 34 colleges requiring four years study and three courses of lectures, 11 requiring four years study, 4 requiring four courses of lectures, and 17 will require three courses of lectures in the fall of 1891. Thus the list of colleges in the United States that require but two courses and have no provision for longer study is reduced to 21. Before 1868 there were none. A number of States will not permit physicians to practice within their limits unless they have attended three courses of lectures. The percentage of graduates to matriculants was 35.8 in 1881–82 and 30.1 in 1890. The percentage in Canada has not reached twenty-four in ten years. These figures are signs of a rapid advance in the last few years, an advance that is sweeping all opposition before it. Dr. John B. Rauch, Secretary of the Illinois State Board of Health, in his admirable report from which the foregoing statistics emanate says, "The movement for a higher standard of medical education has now acquired

a momentum that will probably result in the control of medical education and the regulation of medical practice in every State and Territory (except, perhaps, Alaska), during the present decade. The indications are that in the course of another year at least 100 colleges in this country will require four years study."

The practical lesson of these facts is that every practitioner should do all in his power to help the cause along. One thing all can do, and that is use their influence to obtain the passage of good medical practice acts and their subsequent enforcement. Connecticut, Kansas, Maine, Maryland, Massachusetts, Ohio, Rhode Island, Texas, Utah, and the District of Columbia, either have no law whatever governing the practice of medicine, or else the law is inoperative. Arizona, Delaware, Georgia, Idaho, Indiana, Michigan, Nebraska, Nevada, and Wyoming require simply a "registration of diploma" with some county or State officer. Let the medical men of any of the above States read the medical practice acts of Minnesota or Illinois and then their own, and see how far behind the times their respective States are. It may be an incentive to work.

THE EXPERIMENT WITH THE DOG.

The novel experiment of grafting a bone from a dog to that of a human being has naturally commanded a great deal of attention in medical, as well as lay circles. In the latter, however, it has received even more than its share of notice from anti-vivisection enthusiasts, who have circulated absurd sensational reports concerning it in the daily press. Whatever publicity has been given to the operation, it is due to the experimenter to say that he has been in no way, directly or indirectly, connected with it. With an honest and humane purpose of benefiting a hopeless cripple, and with a becomingly tender regard for the lower animal, Dr. Phelps determined upon a new departure in surgery, the results of which are given elsewhere in our columns. He had, apparently, sufficient grounds after careful investigation of the issues at stake to warrant a trial of his theory. Notwithstanding actual union of bone with bone did not occur, such a possibility, with different conditions and surroundings, is reasonably hopeful. In this particular instance sufficient time was not allowed for the completion of such a process. An interesting fact, however, was that the soft parts promptly responded to the effort, and demonstrated not only that tissues of different species could be made to unite, but that a circulation could also be established between animals of different species without danger to either.

The application of the principle to reparative surgery is one which may open a field for future study and experiment and may result in wide ranged usefulness to humanity. The possibilities in these directions obviously cannot yet be determined, until better means and opportunities are afforded to secure the end. If, hoping beyond this, we can look forward to a corresponding union of more solid parts, if bone can be made to grow to bone, the advance in the treatment of ununited fracture will be pronounced and radical. In view of the good that may accrue from success in similar trials they should not be abandoned merely to satisfy the demands of the so-called humane societies. The charge of cruelty to animals no longer applies to experimentation in these directions. Even in the instance in question, which has been so severely and unjustly criticised by the sensational press, the operation was earnestly solicited by the patient. The animal from beginning to end suffered no pain, nor appreciable discomfort aside from restriction of movements.

It is true the dog lost a paw, but it was in a worthy cause. The value of a dog's leg compared with that of a human limb and possibly a human life, should not admit of any argument. If we contrast the care for the comfort of the animal with the treatment which she might receive upon the street, with the ruthless dog-pound at the end of her career, there can hardly be a question that she received the merited reward of a higher and nobler mission than that of a simple cur born to be kicked, starved, and finally choked.

PHTHISIS AND THE BACILLUS.

Drs. Heneage Gibbs and E. L. Shurley have recently published their views again with regard to the nature and treatment of phthisis pulmonalis. These gentlemen, as is known, feel some doubts as to the bacillus being the essential factor in causing this disease, or at least certain forms of it. We cannot find, however, that they yet have reached a very definite stage in their inquiry. It is, we believe, quite generally admitted that there may be a non-bacillary phthisis, but Drs. Gibbs and Shurley do not tell us exactly what it is, or how to recognize it. They believe also that the destructive and inflammatory disturbances of the lungs are the result of some bio chemical poison. In this respect, it seems that they are only confirming what has been believed by others, and what Koch's "tuberculin" apparently proves.

The treatment advocated by the gentlemen referred to consists in the inhalation of chlorine gas and hypodermic injections of gold and iodine. It would be interesting to know whether experiments have been made to determine how much chlorine gas can be made to permeate the deeper air-passages in the lungs. It seems at first sight that a practically irrespirable gas could not be gotten into the bronchioles or alveolar spaces in sufficient quantity to have a decided antidotal effect. However, we await the announcement of the results. So far, we note that among twenty-two cases treated there have been six apparent cures.

THE DISTRIBUTION OF ANATOMICAL MATERIAL.

A bill has passed the State Senate which provides for the equable distribution of dissecting "material" among the post-graduate schools and colleges of the State. Heretofore, the undergraduate institutions alone have been entitled to a share, and they have shown a good deal of unfriendliness toward the post-graduate institutions; the present bill, it is believed, will remedy the injustice, and correct some other well-known abuses connected with the distribution of the pauper dead.

News of the Week.

Twins Five Times.—Dr. M. H. Turner, of Hammondsville, N. Y., in detailing the results of a large and varied obstetric experience writes that he has "just delivered Mrs. D—— of her fifth pair of twins." Dr. Turner was in attendance upon the good mother on four similar occasions. We trust he will be on hand at the next.

West End Medical Society, New York.—At the annual meeting of the West End Medical Society, held on Saturday evening, February 7, 1891, the following officers were elected for 1891: *President*, Dr. E. J. Ware; *Vice-President*, Dr. F. J. Bowles; *Secretary* and *Treasurer*, Dr. F. Spencer Halsey.

Further Experiences with Tuberculin.—Mr. Jonathan Hutchinson in a lecture on lupus says that no cure of this disease by means of Koch's lymph has yet occurred in London. Virchow has recently shown to the Berlin Medical Society the specimens taken from the body of a man, aged fifty-four, who had been admitted to the Charité as an in-patient on October 6th of last year, suffering from pleurisy, and whose condition had been satisfactory up to November 20th, when treatment by Koch's remedy was begun. There was no fever, no loss of weight. Since November 20th five injections of 5 milligrammes each had been given, followed each time by powerful reactions. After the last injection (January 9th) fever set in, which persisted until death (January 20th). Post-mortem examination showed, besides old-standing induration in the lungs and remains of the pleuritic condition, an exceptionally wide-spread miliary tuberculosis, extending over the lungs, the spleen, the kidneys, and the liver. Professor Ewald has made a report upon his experiences with Koch's lymph in the Augusta Hospital. One hundred and fourteen cases had undergone the treatment at this establishment, the total amount of lymph used being 32,000 milligrammes. Ewald summed up as follows: "Gentlemen, if I am openly to express my conviction, I must say that I have not yet seen a single case that I could really call cured." He stated, however, that in a certain number of cases the improvement following the injections had been greater than had ever been known to result from any other remedy in so short a time. Dr. James Israel, Surgeon to the Jewish Hospital, gave an account of 24 surgical tuberculous cases treated by the lymph during from thirty to sixty days. One case of hydrops tuberculosis of the knee he pronounced to be cured; 2 cases ended fatally; 5 cases, 1 of which was lupus, remained absolutely uninfluenced by the treatment, the injections, though followed each time by the well-known general reaction, producing neither local reaction nor even the slightest beginning of any therapeutic effect; 1 case of tuberculosis of the prostate showed neither general nor local reaction even after injections of 4 centigrammes, nor any change of condition; 6 cases showed decided improvement, 5 showed no improvement, 2 cases relapsed, and 3 became decidedly worse. Dr. Israel gave a detailed history of three of his cases, which were specially interesting, and, in conclusion, summed up as follows: 1. The remedy does not in all cases, even if we exclude caseous foci, exert an influence on tuberculous tissue. 2. The remedy does not always produce decided necrosis, but sometimes inflammatory phenomena also. 3. The intensity of the local reaction bears no proportion to the intensity of the general reaction. 4. The intensity of the local reaction is no criterion of the therapeutic effect. Good effects may be achieved where the local reaction is feeble. Intense local reaction may be unaccompanied by any favorable therapeutic effect.

A New Medical School in Paris.—There is a scheme on foot to start a rival medical college in Paris, the faculty to be composed of various hospital surgeons and physicians. It is said that the professors in the regular faculty neglect to use the hospitals for teaching purposes.

A Curious Way of Getting Lupus.—Dr. B. Baginsky has shown a patient who after making use of a handkerchief belonging to her phthisical sister was attacked by lupus of the nose.

Treatment of Tuberculosis and Phthisis by Koch Lymph.—Dr. W. Körte, Surgical Director of the Urban Hospital, has reported on twenty-eight cases of surgical tuberculosis that have been treated by him on the Koch method. A decisive result had not been obtained in any case. Not a single case was cured, but many improved. He had gained the impression that the patients were gravely affected by the treatment, and that many lose ground in spite of the best nourishment. With many cases of death that had no causal relation to the treatment, there was one that was suspicious. In the case of a child, four years of age, that had received injection on account of a tuberculous knee-joint affection, a fresh tubercular meningitis was found after death, which had taken place rather suddenly. In the knee-joint itself, however, there was no fresh eruption of tubercle. Professor Sonnenberg has shown a case of advanced phthisis that had been treated by the combined surgical and Koch methods, as Koch himself had suggested. The lung had been opened and treated by cauterization and iodoform packings in the manner mentioned in a late communication. The patient had a remarkably rapid and satisfactory recovery, although it would be too much to say that a cure has been achieved.

No Lymph.—Mrs. Blinkers—"I hear Dr. Curem has got back from Berlin. You must go around at once and see if he obtained any of Professor Koch's lymph." Mr. Blinkers—"He couldn't get any. I met him in the street." "Did he tell you he couldn't get any?" "No; but he told me he had doubts of its curative properties." —*New York Weekly.*

The Duty on Dentures.—Our esteemed contemporary *The Evening Post*, is in a state of mind because certain materials pertaining to the manufacture of teeth have had a tariff of fifty-five per cent. *ad valorem* placed upon them. As the *Post* mildly puts it: "the dentists have been swindled in a dastardly manner." We feel very sorry about the duty and about the *Post*. Perhaps in some providential way, however, the crime may be atoned for and a serious dental catastrophe averted. With cheap silver, for example, amalgam plugs will be cheaper and that may offset the swindle.

To Bring out Râles in a case of suspected phthisis, give the patient iodide of potassium for two days.

Dead Issues.—A discussion is about to be undertaken between *The Sanitarian* and an "eclectic" journal called the *Medical Tribune* on the value of vaccination.

The Woman's Hospital of this City has received from Mrs. Morris K. Jesup the sum of $100,000. It is considering the plan of erecting new hospital buildings on a different site from the present.

Scotch Physicians Threaten a Strike.—A largely attended meeting of medical men was held in Edinburgh recently to debate the grievances of over-work and under-pay so long felt and hitherto so patiently borne. Practitioners from Ross-shire, Argyleshire, Dumfriesshire, Inverness, Dundee, John o' Groat, Tobermory, as well as Edinburgh and the mining districts, were present. There was a strong feeling shown in favor of "striking" for higher fees. This very unwise course, however, did not prevail, but the matter was referred to committees for further investigation.

Inoculation of Dog Serum as a Remedy for Tuberculosis.—In a series of communications made in the course of the last two years to the Société de Biologie, MM. Héricourt and Richet have given the results obtained by the injection of the blood of an animal refractory to tuberculosis, such as the dog, into the economy of one susceptible to the onslaughts of the bacillus. They have demonstrated experimentally that such a proceeding exerts a retarding influence on the evolution of tuberculosis artifically communicated, without, however, stopping it altogether. With a view of intensifying these partially protective properties of canine blood, they inoculated the dog with a large dose of very active tuberculous matter, and one month later (the animal having lost flesh, and exhibiting manifest signs of ill health) injected into the peritoneal cavity of three rabbits 70 c.c. of the dog's blood. A week later these rabbits were, with three other test rabbits, inoculated with strong tuberculous virus, with the result that in twenty-five days two of the latter had succumbed, the rest surviving. Their ultimate fate is not recorded. Encouraged by these results, MM. Héricourt and Richet have extended the application of their method to tuberculous human beings, employing the serum only, and selecting the interscapular region as the seat of inoculation. M. Richet reports (Société de Biologie, January 24th) that four phthisical men have, since the early part of December, 1890, been subjected to this novel treatment. The results obtained seem to warrant the assumption that the introduction of the serum of dog's blood into the human economy counteracts, to some extent at least, the noxious influence of Koch's bacillus.—*Paris Cor. of Lancet.*

The New York Anti-Smoking Law, which went into effect September 1, 1890, reads as follows: "No child actually or apparently under sixteen years of age, shall smoke or in any way use any cigar, cigarette, or tobacco in any form whatever, in any public street, place, or resort. A violation of this subdivision shall be a misdemeanor, and shall be punished by a fine not exceeding $10, and not less than $2, for each offence." It doth not yet appear whether public sentiment will enforce the law. This law is proper enough in its aims, but it is a question if it can or will be enforced. Possibly the County Medical Society, which looks after the school children quite sharply, may be induced to attend to the young cigarette fiends, and those who supply them.

Lectures to Mothers and Nurses.—A free course of weekly practical lectures to mothers and nurses has been begun at the New York Post Graduate Medical School and Hospital. Among the subjects and lecturers are the following: "The Care of the Eye," by Dr. D. B. St. John Roosa; "The Most Frequent Surgical Incidents of Infancy and Early Childhood," by Dr. Robert Abbe; "The Care of the Skin in Health and Disease," by Dr. L. D. Bulkley; "Practical Points in the Nursing at the Babies' Wards as Employed in Lung Diseases, Fevers, Intestinal Diseases," etc., by Dr. Henry D. Chapin; "Infant Feeding and the General Care of Young Children," by Dr. J. H. Ripley.

The Unity of the Infectious Fevers.—Dr. Ernst Roger, of Potsdam, as the result of a long and careful study of infectious fevers in the cadet barracks at Potsdam, has reached some novel conclusions. He holds, for example, that because there is a general agreement as to the period of incubation in such diseases as scarlet fever, measles, rötheln, diphtheria, and mumps (with perhaps the exception of measles), and because all of them have many features in common, they are all species of mixed infection in which there is a common organism, and that the special modifications in each disease are the results of the presence of certain other specific bacteria. He holds that this common organism under certain circumstances loses its virulence, and regains it when placed under favorable conditions; that it and the other organisms which play a prominent part in the production of the special symptoms produce poisonous substances which may cause rapid intoxication of a patient, while through the spores that are formed the infection may be transferred to others, or they may give rise to a second crop of the organism in the original host (auto-infection); that the producers of the mixed infection belong to the suppuration-causing group; and that they give rise to different symptoms and pathological conditions according to the tissues that they attack—the glands of the skin, the subcutaneous connective-tissue, lymphatic glands, and lymph vessels, the mucous membrane, the serous surfaces, or other elements of special organs. Roger's views are fortified with a long array of tables and statistics.

The Ricord Prize.—The French Academy of Medicine has been authorized by the Minister of Public Instruction to accept the legacy devised to it by Philippe Ricord, for the foundation of a prize, to be awarded every two years to the author of the best work on venereal disease which appears in the intervening period.

A New International Clinique at Paris.—A number of medical men in Paris have formed themselves into a society called the Society of Medical Assistance to Foreigners, for the purpose of, 1, organizing a system of hospital relief to all foreigners; 2, to give them gratuitous consultation; and, 3, to take advantage of the clinical material which will be thus collected to give practical instruction in all the branches of medical art.

Regulating Embalming.—A bill has been introduced into the New York Legislature to establish a Board of Embalming Examiners of the State of New York, and to regulate the practice of embalming human bodies.

In Massachusetts the Medical Examiners have issued an order providing that no body shall be embalmed nor any embalming fluid be used on the body until a physician's certificate of the cause of death be obtained.

A Negro Pension Surgeon.—The *Indiana Medical Journal* is much disturbed because a negro physician has been appointed on the Examining Board for Pensions of Indianapolis.

A Jersey City Medical College.—The District Medical Society of the County of Hudson, N. J., has passed the following resolution:

Whereas, A certain medical institute, called the "Medical and Surgical College of the State of New Jersey," chartered by special Act of this State, approved March 17, 1870, was organized during the year 1888, and opened in three small rooms on the top floor of the General Office building, Jersey City; and

Whereas, The State Board of Medical Examiners of New Jersey will introduce a bill at the next meeting of the Legislature for the purpose of repealing said charter;

Be it resolved, That the District Medical Society for the County of Hudson does hereby earnestly protest against the existence of said alleged college as an unnecessary, inadequate, and disreputable institution, tending to degrade and lower the standard of the medical profession; that the influence of this Society and of the individual members thereof be given to the support and passage of the bill to repeal said charter, and that a copy of this resolution be forwarded to the several medical societies of this State, with requests for their support and influence for the passage of said bill.

A State Medical Library.—At the recent annual meeting of the Regents of the University of the State of New York, on the motion of Dr. William H. Watson, the following resolutions were adopted: That we accept from the Albany Medical College the gift of its medical library of five thousand volumes, undertaking to give the same convenient space and proper care, and to keep them open to the public during the same hours as the State law library; and, That the Regents establish a medical department of the State library, and that the Legislature be asked to appropriate a suitable sum for its proper maintenance.

The New Building of the Woman's Medical College of this city was opened for the reception of visitors on February 14th. The sum of $63,000 has been raised already to defray the building expenses, and a debt of $12,000 remains. This, it is hoped, will soon be raised. Perhaps it would be obtained sooner if the worthy Dean were not giving her influence toward raising money for another medical college not yet existent.

The National Association of Medical Colleges.—The following gentlemen are named as the Committee on Organization and By-laws of the National Association of Medical Colleges: Dr. P. H. Millard, of St. Paul, Chairman; Dr. William Osler, of Philadelphia, and Dr. Samuel Logan, of New Orleans. The committee will report at the forthcoming meeting to be held in Washington.

A New Cure for Cancer.—Professor Mosetig, of Vienna, announces that in pyoktanin or methyl-violet, he has found a remedy for cancer. He does not assert that any cases are quite cured yet; but the results have been so satisfactory as to lead him to think a cure will be found in the aniline dyes.

Infectious Diseases and the Telephone.—In some hospitals it is customary to allow visitors to converse on certain days, by means of a telephone in a waiting-room, with patients in the wards, and this arrangement has been found to work admirably in allowing communication without possibility of contagion.

The Death of Dr. Elisha Sterling, of Cleveland, O., is announced, at the age of sixty five. Dr. Sterling was well known as a naturalist, and to him is given the credit of being the father of fish-culture in this country.

Dr. Edwin Hazen, one of the oldest and best-known physicians of Vermont, died at his home in Woodstock recently. Dr. Hazen had been in the continuous practice of medicine for half a century.

A Curious Piece of Paternalism.—The Russian Government has prohibited the sale of "spermin" by pharmacists, even when prescribed by a medical man. "Spermin" is said to be an inert body.

Sterilized Milk still Prone to Decomposition.—Sterilized milk is, according to Dr. Marr, as badly borne in children's dyspepsia as ordinary milk. Even when sterilized by Soxhlet's apparatus, milk is still prone to decomposition, and hence favors the decomposition processes which are active in the diseased digestive tract.

Animal vs. Human Lymph.—In reply to the question propounded by the Board of Health of the Department of the Seine by the Préfet of that territorial division, as to the advisability of substituting animal for human lymph in vaccination, Dr. Lancereaux, specially deputed to report on the subject, pronounces decidedly in favor of the animal product, and recommends the discontinuance of human lymph. The reasons adduced in support of this conclusion are the immunity from risks of communicating syphilis, erysipelas, lymphangitis, etc., and the greater facility of procuring the calf lymph in a pure state, the source being picked animals placed under the most favorable hygienic conditions. M. Lancereaux attributes to the general employment of calf lymph the increasing favor with which the practice of vaccination, and especially revaccination, is regarded in France.

Medical Legislation in California.—The California Legislature has now before it a large amount of medical legislation, the general tendency of which is to regulate pretty nearly everything. There is a bill providing for the appointment of a State Veterinary Surgeon; also a bill providing for the regulation of the practice of pharmacy and sale of poisons.

Another bill proposes to establish a State Board of Funeral Directors and to regulate the practice of undertaking.

A bill has been introduced appropriating $80,000 for the Medical Department of the University of San Francisco, and we hope the university will get the money.

A bill has been introduced, also, forbidding the sale of cigarettes to boys, and another regulating the practice of veterinary medicine.

Reviews and Notices of Books.

Laboratory Manual of Pharmaceutical Chemistry. By Oscar Oldberg, Pharm.D. (Professor of Pharmacy, Northwestern University), and John H. Long, Sc.D. (Professor of Chemistry, Chicago Medical College). Second edition, revised and enlarged. 8vo, pp. 457. Chicago: W. T. Keener. 1891.

The principal changes in this edition are a new chapter on "Urinary Sediments," and the rewriting of that on "Chemical Analysis of the Urine." The work is designed to afford an introduction to the study of pharmaceutical chemistry, and while primarily intended for those who are to be druggists, contains, nevertheless, much of interest and profit to the medical man. Different sizes of type distinguish the main outlines under each heading from the ensuing discussions and technical details. The general typographical appearance is most attractive. We believe that several more editions will be called for before the usefulness of the work will be exhausted.

Transactions of the Association of American Physicians. Fifth Session; Held at Washington, D. C., May 13, 14, and 15, 1890. Volume V., pp. 272. Philadelphia: Printed for the Association by Dornan.

The high standing of the Association vouches for the worth of its volumes of transactions. This last one contains nineteen excellent papers. Professor W. T. Lusk writes on antiseptic midwifery, giving, among other things, the plans carried out in the Bellevue Hospital lying-in pavilion. Dr. Francis P. Kinnicutt contributes an admirable paper on the methods of physical examination in diseases of the stomach. Professor F. C. Shattuck writes on the same subject from a decidedly conservative stand-point. Dr. J. E. Reeves has an interesting and instructive article on typhoid fever, in which he cites five cases of perforation with recovery. The long and spirited discussion that followed this paper is also given. The method of limiting the prevalence of tuberculosis is treated by Dr. E. O. Shakespeare, and discussed by several others. There are also very interesting and valuable papers by Professors C. L. Dana, A. A. Smith, Norman Bridge, William Pepper, D. W. Prentiss, R. H. Fitz, and J. E. Graham, and by Doctors I. N. Danforth, S. Weir Mitchell, E. L. Trudeau, W. Sinkler, C. F. Folsom, I. T. Dana, and J. P. Crozer.

A Clinical Study of Diseases of the Kidneys. Including Systematic Chemical Examination of Urine for Clinical Purposes; Systematic Microscopical Examination of Urinary Sediments; Systematic Application of Urinary Analysis to Diagnosis and Prognosis; Treatment. By Clifford Mitchell, A.M., M.D. Chicago: W. T. Keener, 96 Washington Street.

This is mainly interesting from the fact that it is by a homœopath, and from a homœopathic stand-point. It has several good points. First, it is clearly printed and handsomely bound; secondly, the section on urinary analysis, though neither complete nor new, is easy of execution by the general and busy practitioner; thirdly, the application of urinary analysis to diagnosis is clearly set forth, and the rules given are of considerable value. As a rule, most books on this subject have too much chemistry and not enough medicine, or vice versa. This work, however, is well balanced in this respect.

Micro-organisms of the Human Mouth. By Willoughby D. Miller, D.D.S., M.D., Professor at the University of Berlin. 8vo, pp. 364. Philadelphia: The S. S. White Dental Manufacturing Co. 1890.

Some idea of the thoroughness with which this work has been prepared is gained by a glance at the Bibliography, which contains about two hundred and fifty references. Part I. of the volume comprises general bacteriological studies, with special reference to the bacteria of the human mouth. A brief but comprehensive discussion is given of the forms of bacteria, their origin, reproduction, life conditions, and their behavior toward various chemical and physical reagents. Their vital manifestations are given at some length. No less than seven substances found in the mouth serve as nutrient media for their reproduction. Among these are the normal saliva and mucus, softened dental tissue, and accumulated particles of food. Full directions are given for the proper conduct of studies and experiments along the lines indicated. Chapter VII. is entitled "Original Investigations on the Decay of the Teeth," and naturally attracts the most attention. Part II. treats of the "Pathogenic Mouth Bacteria and the Diseases which they Produce."

We have not space to speak in detail of Dr. Miller's conclusions. They are of interest not only to dentists, but to all engaged in bacteriological work. From his name we conclude that he is an American, and we are glad to have such an able representative at one of the largest and most famous of the European universities.

Proceedings of the National Conference of Charities and Correction at the Seventeenth Annual Session, held in Baltimore, Md., May 14–21, 1890. Edited by Isabel C. Barrows, Official Reporter of the Conference. Pp. 476. Boston: Press of George H. Ellis.

Anyone interested in the organized forms of charity—hospitals, training-schools for nurses, insane and orphan asylums, prisons, immigration bureaus, etc.—should have this book. It contains a large number of papers on these matters by the best authorities in this country. Especially noteworthy are the following: "State Boards of Charities," F. H. Wines; "The Economic and Moral Effect of Public Out-door Relief," Mrs. C. R. Lowell; "The Moral Imbecile," Dr. I. N. Kerlin; "The Care and Treatment of the Insane," Dr. Richard Gundry; "Prison Discipline," H. F. Hatch; and the several papers on hospitals and training schools for nurses.

A Manual of Weights and Measures. Including Principles of Metrology, the Weights and Measures now in Use, Weight and Volume and Their Reciprocal Relations, Weighing and Measuring, Balances (Scales) and Weights, Measures of Capacity, Specific Weight, and Specific Volume, etc., with Rules and Tables. By Oscar Oldberg, Pharm.D., Professor of Pharmacy and Director of the Pharmaceutical Laboratory in the Illinois College of Pharmacy, the Department of Pharmacy of the Northwestern University. Third Edition. Revised. Chicago: W. T. Keener.

Two large editions of Dr. Oldberg's work being exhausted, the third, thoroughly revised, corrected, and brought up to date, is issued. It is a standard work on the subjects treated, a fair index of which appears in the title. The adoption of the metric system of weights and measures in the Pharmacopœia, to the exclusion of all other systems, renders a thorough knowledge of that system almost imperative. Such knowledge can be had in the work under review. It is an invaluable text-book for students, and an unusually useful reference book for the practitioner, the chemist, and the pharmacist.

Transactions of the Intercolonial Medical Congress of Australasia. Second Session. Held in Melbourne, Victoria, January, 1889. Illustrated. Pp. 1,029. Melbourne: Stillwell & Co.

This is a portentous volume containing two or three hundred papers by the brainy physicians of Australia. Naturally many of the papers are of local interest, but the great bulk will be found of interest to the profession in general. The articles on typhoid fever, diphtheria, hydatid disease and on gynecology and pharmacology are especially worthy of note.

Wood's Medical and Surgical Monographs. November Issue. Contents: "The Treatment of Uterine Affections by Massage," by Dr. Eugene Arendt; "Cosmetics, a Treatise for Physicians," by Dr. Heinrich Paschkis; "On Affections of the Stomach in Diseases of the Male Genital Organs," by Dr. Alexander Peyer. Pp. 508. Price, $10 a Year. Single Copies, $1. New York: William Wood & Co., 56 and 58 Lafayette Place.

The November issue is fully up to the high standard of the now famous monographs, and will be warmly welcomed and widely read. In his essay on massage in uterine affections, Dr. Arendt gives an interesting and lucid description of Thure Brandt's methods, which have had surprisingly good results in the hands of many physicians. The movements are modified from the Swedish system and, as a rule, tend to lessen the blood supply of the pelvic viscera. The system is worthy of careful study and trial. The article on cosmetics by the renowned Vienna physician Dr. Paschkis is of infinitely more value than its title indicates. After a most interesting historical sketch of the subject, the author devotes two hundred pages to describing the proper care of the skin, hair, nails, teeth, etc.; a care that is scientific as well as pleasing. The latter quality is one which is too often unknown or neglected by the profession. The art of prescribing agreeable applications often brings popularity as well as dollars. Dr. Peyer's article is invaluable in accentuating an important etiological factor in stomach troubles, a factor that is much too often overlooked. The author cites three hundred cases of gastric disorder that were due to diseases of the genital organs, among them, dyspepsia, nausea, anorexia, vomiting, flatus, and cramps. His deductions are valuable.

Transactions of the Medical Society of the State of California. Session of 1889. Pp. 290. San Francisco: Woodward & Co.

If anybody imagines that the science of medicine is confined to the East, he should read the transactions of this society, which is the largest west of the Rocky Mountains. They show that California is abreast of the times and, by original investigations, is making rapid advancement in every branch of medical science. The papers are both readable and valuable.

The Medical News Visiting List for 1891. Weekly (dated, for 30 patients); Monthly (undated, for 120 patients per month); Perpetual (undated, for 30 patients weekly per year); and Perpetual (undated, for 60 patients weekly per year). The first three styles contain 32 pages of data and 176 pages of blanks. The 60-Patient Perpetual consists of 256 pages of blanks without data. Each style in one wallet-shaped book, pocket, pencil, rubber, erasable tablet, etc. Philadelphia: Lea Brothers & Co. 1890.

The new issue maintains its previous reputation. It adapts itself to every style of book-keeping; there is space for all kinds of professional records; it is furnished with a ready-reference, thumb-letter index, and has a most valuable text.

Transactions of the Medical Society of the State of Pennsylvania at its Fortieth Annual Session. Held at Pittsburg, 1889–90. Vol. XXI. Pp. 338. Philadelphia: William J. Dornan.

This volume is a credit to the society, progressive and scholarly. Among the contributors are Professor James Tyson and Professor James M. Duff and Drs. John Aulde, Henry Wharton, Samuel Ayres, and J. A. Lippencott. These names alone vouch for the excellence of the volume.

Transactions of the Eleventh Annual Meeting of the American Laryngological Association. Held in the City of Washington, D. C., May 30 and 31, and June 1, 1889. Pp. 150. New York: D. Appleton & Co.

The best talent in the laryngological specialty is embraced in the American Association and its meetings annually bring forth many valuable papers. The twenty one read at the last meeting are reproduced in full, with discussions and handsome illustrations, in the work under review.

Railway Surgery. By C. B. Stemen, A.M., M.D., LL.D., Professor of Surgery in the Fort Wayne College of Medicine; Surgeon to St. Joseph Hospital, etc. Pp. 315. Fifty-three Illustrations. St. Louis: J. H. Chambers & Co. 1890.

This work has been written for the use of railway surgeons, of whom, we are told, there are now some twenty-five thousand in this country, and will doubtless prove a handy book for the class of emergency work that comes in their way.

Post-Mortems. What to Look For and How to Make Them. By A. H. Newth, London. Edited, with numerous notes and additions, by F. W. Owen, M.D., formerly Demonstrator of Anatomy, Detroit College of Medicine. Cloth, 12mo. Detroit, Mich.: The Illustrated Medical Journal Co.

Few general practitioners can make a good systematic necroscopy. It requires practice and a broad, general knowledge. This manual will make up for a large deficiency in both these points. It is a reminder to the best of educated physicians and a good guide to the student. It is not to take the place of large works on pathology, but presents, in a clear manner, all the important conditions of the organs met with in post-mortem examination, either in health or disease. There are also chapters on the post-mortem appearances seen in those drowned, poisoned, hanged, and in cases of infanticide. It is small and convenient and will prove of great value to all who have occasion to use it.

Physical Diagnosis and Practical Urinalysis. An Epitome of the Physical Signs of the Heart, Lung, Liver, Kidney, and Spleen in Health and Disease. Edited by John E. Clark, M.D., Professor of General Chemistry and Physics in the Detroit College of Medicine. Pp. 193. Fully Illustrated. Detroit, Mich: The Illustrated Medical Journal Co.

Dr. Clark thought that a work on physical diagnosis was needed for students in which the main points would be briefly and plainly expressed. He has succeeded in producing such a work in the book under review. The entire subject is embraced in one hundred pages, and very clearly and thoroughly is it treated. Not only students but practitioners as well will find the book valuable. The chapters on "Urinalysis" are original, and embrace the doctor's laboratory processes, used in teaching this branch of medicine in the Detroit College. His methods are clear, practical, and easy of execution. There is also a valuable chapter on "Bacteria."

Treatment of Furunculosis.—Dr. Veiel, at the annual meeting of German physicians held at Bremen, stated that he had used in the treatment of furunculosis a paste consisting of equal parts of oxide of zinc and vaseline, to which was added four per cent. boric acid. This ointment was thickly spread on lint. In cases of circumscribed furunculosis the paste was rubbed in and around the diseased parts three times daily. If the affection were universal, the whole body was rubbed with the application. Sublimate baths were at the same time used when the patient could bear them. In a case of universal furunculosis a perfect cure was obtained in seven weeks. Large boils were poulticed.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

KOCH'S TREATMENT—THE RELATIONSHIP OF LUPUS TO TUBERCULOSIS—MR. HUTCHINSON ON THE VALUE OF KOCH'S METHOD IN LUPUS—DISCUSSION ON THE VALUE OF VENESECTION—RELICS OF JOHN HUNTER—SMALL POX MORTALITY IN LONDON IN 1890—DEGREES IN HYGIENE.

LONDON, January 31, 1891.

KOCH'S treatment is at present somewhat at a discount here. The facts recently brought forward by Professor Virchow are indeed such as to induce caution in using the remedy. Clinical observers also are finding the ultimate results of the treatment to be far from satisfactory. The patient with lupus who was taken to Berlin by Dr. Pringle and Mr. Malcolm Morris, is now almost as bad as ever. The case of supposed tubercle of the iris treated by Mr. Watson Cheyne has steadily become worse in spite of the treatment, so that the organ has been excised. On examination, the growth has proved to be tubercular, and, as such, it is disappointing that the injections failed to cause any improvement. The only points on which it can be said that any unanimity of opinion exists as yet, are as to the value of the remedy in diagnosis, and also in regard to its having established on a firmer basis the view that some very close relationship exists between lupus and tuberculosis. In his recent lectures on lupus (in the London Post-Graduate Course), Mr. Hutchinson expressed a very decided opinion that clinical facts did not favor the belief that infection with the tubercle bacillus was the sole and efficient cause of the disease which we called lupus. Alluding to the marked effects of the injections upon lupoid tissue, Mr. Hutchinson remarked that all diseases of the lupus family were liable, when inflamed, to have the inflammation assume the character of erysipelas. Many observers had noted this, and it had also been generally agreed that after attacks of erysipelas the lupus was usually in a much improved condition. He had himself always been accustomed to hail erysipelas in lupus (except in lupus erythematosus) as a direct gain to the patient. This fact must be borne in mind when examining the results of Koch's treatment. Mr. Hutchinson mentioned some cases (one under his own care) in which the injection of Koch's fluid produced no effect whatever on the patches, though the temperature rose. In all the cases he had heard of in which the lupus patch had been made to inflame, the results, as regarded its subsequent improvement, had been good. No one, however, ventured to report an instance of complete cure of the cases which had been shown to him as the most satisfactory; he was bound to say that in every one there had been evidence, at some part of the edge, of the remains of lupous tissue, ready, probably, to start into fresh growth on the slightest provocation. The treatment did not always influence the essential element of lupus. The brown apple-jelly-like deposit, which was universally acknowledged as the most characteristic of the lupus conditions, sometimes remained untouched even when the inflammatory swelling of the parts had been quite got rid of. The cases which appeared to derive the greatest benefit were those in which there was most of inflammatory swelling, and in which the more specialized elements of the lupus process were least abundant. Should future facts confirm this, we should be obliged to suspect that the remedy was, after all, one for certain conditions of the inflammatory process, and not for tuberculosis. Even then, however, it was possible that it might still prove of great help to us in the treatment of certain forms of lupus. He was not aware that it had yet been tried in any of the cases of what had been described as perfectly "quiet" lupus. On lupus erythematosus a good many experiments had been made. It was foretold by those who believed that what they called "true" lupus was bacillary, and that lupus erythematosus was not so, that the fluid would have no effect on the latter. This prognostication had in the main been fulfilled.

The last meeting of the Medical and Chirurgical Society was devoted to discussing the subject of venesection. Dr. Pye-Smith read a paper in which he gave an account of nearly fifty cases in which he had used bleeding from the arm. This number comprised cases of bronchitis, acute and chronic broncho-pneumonia, lobar pneumonia, miliary tuberculosis of the lungs, valvular disease of the heart, pericarditis, Bright's disease, aneurism, apoplexy, and epilepsy. He expressed the opinion that the remedy was useful—not as one adapted for any particular disease, but in meeting certain indications of pathological states. These indications were: 1, Cyanosis, with distention of the right side of the heart, whether from pulmonary or from some other obstruction to the circulation; 2, intense pain in aortic aneurism; 3, uræmic and prolonged epileptiform convulsions.

Dr. Stephen Mackenzie said he had himself always been in the habit of bleeding for certain conditions, and particularly in the first class of Dr. Pye-Smith's cases—that of distention of the right side of the heart—when life was in jeopardy and where the pulse was slow and feeble. Here relief was immediate and benefit might be permanent. The diseases were of various kinds, such as heart disease, capillary bronchitis, and pneumonia, in which the right side of the heart was endeavoring to get blood through the lungs. He had known life to be saved in hæmoptysis by bleeding; the hæmoptysis ceased and the patient recovered. Marked venous congestion, with cardiac struggling, were the indications for bleeding. In aneurisms there were other means of obtaining the same result, but if potassium iodide, nitrite of amyl, and nitroglycerine had been used and failed, then that was strongly in favor of this mode of treatment. In uræmic cases he had once been accustomed to bleed, but the results had not been encouraging, and if the cause of the arterial tension was, as he believed, some toxic influence, then he believed the best mode of treatment was by morphine. But in a case with dilated left ventricle, cyanosis, œdema, and suppression of urine, venesection gave such relief that on a recurrence of the symptoms the patient asked to be bled.

Sir George Humphry said that in inflammatory affections, such as acute pleurisy and pneumonia, bleeding was the means of giving immense relief. After injuries of the brain, the result of venesection was often markedly beneficial. He believed the abuse of the remedy had caused its disuse.

Dr. Broadbent said that an additional reason why venesection had been abandoned was because human intellects were dominated by theory rather than by experience. The decision against bleeding had been arrived at from the results in cases of pneumonia—a disease in which it was only of benefit in the early stages. He had been brought up in a school that condemned venesection—a position confirmed by the results he used to see in Paris in cases of rheumatic fever, pneumonia, and other acute conditions—but its proper use had by degrees become apparent to him. He agreed with Dr. Pye-Smith, that bleeding would be very rarely needed in aneurism if iodide of potassium were freely given. In cases of overdistention of the right ventricle of the heart, his experience differed from Dr. Pye-Smith's and Dr. Mackenzie's, in that he had had better results in cases of mitral valve disease (particularly in mitral stenosis) than in cases of bronchitis. In the latter disease he relied more on the use of emetics. With an overloaded right heart, the indication for venesection was forcible cardiac impulse, with a small, almost imperceptible, irregular pulse. The forcible impulse showed the power of the heart's action, and that it was in a position to benefit by the relief given by venesection. In pneumonia the opportunity of benefiting by venesection came quite early. In uræmic convulsions his experience of venesection had been uniform

ly favorable. The convulsions were not, he believed, directly due to the toxic action on the brain, but only indirectly through the high arterial tension produced by the poison, and then venesection acted in the same way as in over-distention of the right side of the heart.

Mr. Hulke and Mr. William Bateman bore testimony to the value of venesection in head injuries. Mr. Hulke also mentioned the case of a woman, with an abdominal aneurism, who found such relief from the abstraction of eight or ten ounces of blood that she used frequently to come to the hospital to be bled.

Mr. George Pollock said he had found bleeding most successful in cases of injury to the chest with fractured ribs, punctured lung, and pneumothorax.

Mr. Hutchinson mentioned a specimen of a cured aneurism in the London Hospital Museum, which had resulted from repeated bleedings. Owing to the prejudice among the public against venesection, other means should, if possible, be tried first. A very easy method of diverting some of the blood from one part to another without diminishing the total quantity, was to move the patient low down in the bed and allow his legs to rest in a hot bath at the foot of the bed.

Dr. Angel Money mentioned another method of determining a flow of blood to a given part, viz., to bandage it with an Esmarch bandage and then rapidly release it, when a considerable reaction set in.

The Council of the College of Surgeons are arranging to have a permanent exhibition of letters and other relics of John Hunter.

Only three patients died in London from small-pox during the past year.

The University of Durham is about to institute degrees in hygiene.

OUR VIENNA LETTER.

(From our Special Correspondent.)

THE WAY EAR DISEASES ARE STUDIED IN VIENNA—THE SCARCITY OF GOOD NURSES—A SAD ACCIDENT IN BILLROTH'S CLINIC — VIRCHOW'S UTTERANCES REGARDING THE KOCH TREATMENT—SCHRÖTTER DELIVERS A POPULAR LECTURE ON THE SUBJECT.

VIENNA, February 1, 1891.

In no department, perhaps, are better opportunities offered the student in Vienna than in Otology. The most prominent teachers are Politzer, Gruber, Urbantschitsch, and Bing. The instruction is all good, but the fame of the two professors first named naturally attracts the most students. Their methods of teaching are in many respects similar, though, in a general way, Professor Politzer is credited with illustrating the therapeutics more carefully, while the student sees, perhaps, more cases under Gruber. For one who has had already some practical experience in the treatment of the ear, Professor Politzer's course offers many attractions and advantages. He speaks German with fluency, and a distinct and cultivated accent. He is an enthusiast on his subject, and untiring in his efforts to explain the phenomena witnessed in each case. He has, moreover, what is most rare among Germans, a working faith in the value of delicacy of manipulation, and his talks give many hints as to painless methods and cautious handling. The clinics are conducted somewhat as follows: Of the patients who present themselves perhaps a dozen are of sufficient interest to merit special examination. These are seated by a row of Argands, and examined by the professor, who with colored crayons draws the pathological appearances rapidly on a slip of paper, which the patient holds. If the cases have been already looked over by the student, he now verifies or corrects his conception of the case; if not, he can trace the conditions illustrated on the charts. Cases requiring catheterization of the tuba Eustachii, paracentesis, removal of polypi, etc., are operated on by the students in turn. Some one case of special interest is then selected, thoroughly explained, and the treatment in all its varieties described and shown. Pathological conditions are fully illustrated by specimens showing the various lesions. Thus one becomes practically familiar with the varied ear diseases which thrive so luxuriantly in this climate.

It is a common saying among the foreigners that Vienna is a good place for the student, but a very bad place for the patient. And there is a bit of truth in this. In the first place, German physicians and surgeons seem not to *individualize* in their treatment, and this is true of private as well as hospital practice. Because nine cases have done well under a cold pack, the tenth case gets it, no matter what personal considerations make the treatment of doubtful expediency. Because an operation has succeeded in individuals able to endure it, it is repeated on others manifestly unable to do so. The patient's interests are in effect secondary to those of the treatment. Brilliant triumphs and lamentable failures are the natural outcome.

Then, good nursing is almost unknown here. Vienna is far behind Berlin in this respect. There the nursing in the best hospitals is in the hands of the Lutheran Sisters, who do nearly, if not quite, as well as our trained nurses. But in the great Vienna hospitals male and female patients alike are given over to the charge of coarse women from the lower walks in life. Very indifferent care is thus given. From private sources about the city I hear also much about the wretched quality of sick-room attendance Foreigners anxious and able to obtain the best care for their sick friends find it impossible to obtain here such as they are accustomed to at home. Old residents state that they always nurse their sick themselves, as trustworthy and capable nurses are so difficult to obtain. Were it not for the extreme unwillingness with which Austrian physicians adopt foreign customs, it would seem that there might be here a good field for a few American trained nurses who could speak German.

I witnessed a few days since a sad accident in Professor Billroth's clinic. A young woman was to be operated on for removal of a goitre. The strictest antisepsis was, as usual, observed, and the enucleation done without any special difficulty. Some trouble was experienced once or twice from hemorrhage proceeding from a large vein at the base of the neck. But this was controlled. The operation was completed, and the specimen was being passed around the amphitheatre; the chloroform had been discontinued, and the operator was busy about some minor detail in the wound, when suddenly the hemorrhage recommenced. Equally suddenly the patient turned white and ceased to breathe. Her head was lowered, and with the remark, "Probably air in a vein!" the surgeon and his assistants addressed themselves to the resuscitation. But for such emergencies the clinic, so well supplied in all pertaining to merely operative work, seemed to have no special appliances. The only means used was artificial respiration. For a moment this promised something, but the few spasmodic efforts at breathing thus excited quickly ceased, and the patient was irretrievably lost. The trachea was then opened, and air blown in by an assistant, to no purpose. No oxygen was at hand, no battery ready till long after death was declared, no stimulants were employed, no heat applied. Probably no means would have rescued this case, as the *post-mortem* demonstrated the existence of air-thrombus. But it was apparent that every means at hand was being employed. A most unpleasant impression was made on all the foreigners present by this tragic spectacle, and one could not but be struck by the unshaken coolness with which the surgeon, after the dead body of his patient had been carried out, proceeded immediately to perform a goitre extirpation on a second case—this time with a happier result.

Virchow's recent article upon the dangers of tubercle dissemination by Koch's injections has made quite as much of a stir here as the latter's publication of his secret. Cases are already at hand illustrating this

danger. For example, Professor Schnitzler, some three weeks ago, began the treatment in a case of laryngeal tuberculosis. Within a short time the posterior pharyngeal wall and vault, which had previously presented no traces of disease, showed pearly nodules and large pea-like masses, which rapidly broke down into ulcers. All the general symptoms were greatly intensified, while the pain and difficulty of swallowing became much more pronounced. It is possible in such cases, of course, that the tubercular foci were already present, but latent, and were simply demonstrated by the treatment.

Professor Schrötter, the laryngologist, delivered a popular lecture, an evening or two since, on the Koch method, which was largely attended by a mixed audience. The following utterances indicate the lecturer's position: "We have so far been unable to observe a cure, or, what is more, improvement in a single case. The action of the remedy cannot be termed curative; the changes observed by me have been of a very unfavorable character, new ulcerative processes being set up in many cases. The dangers cannot be concealed, and among them we must reckon that of infection of distant organs."

While admitting the good effects observed in lupus, the lecturer adds: "We cannot with good conscience recommend the method to any patient"—certainly the most decided public stand as yet taken against the method by any man of eminence here.

AN OLD STORY ABOUT A NEW SYRINGE.

To the Editor of the Medical Record.

Sir: It is of small importance, yet in view of the form of what is now known as Koch's syringe, and the fact that the article in the Medical Record of February 7th, headed "An Improved Method for Administering Hypodermic Injections," is the second presentation of the same thing since I supposed I was presenting it for the first time many years ago,[1] I call your attention to the truth of the old adage, "There is nothing new under the sun." The instrument was made by Shepard & Dudley, and I think is still in their catalogue. Yours,

Edgar Holden, M.D.

Newark, N. J., February 8, 1891.

INSTITUTIONS FOR DRUNKARDS.

To the Editor of the Medical Record.

Sir: In a note in the Record on a State Institution for Drunkards in Massachusetts occurs this sentence: "Such an institution was started in this State at Binghamton, but it utterly failed to accomplish its purpose."

This is one of those curious errors that by repetition becomes a settled conviction in the public mind. Jenner's first application of vaccine was not an utter failure; the use of ether or chloroform were not failures at first; Pinel's removal of the manacles of insane in an asylum was not a failure; the Woman's Hospital in New York was not a failure (although some eminent men asserted that it was a mere personal scheme); the first insane asylum was not a failure, although bitterly opposed by many persons.

Binghamton Asylum was not a failure because it was changed to an insane asylum. It was the first and pioneer asylum of the world; and after a stormy career of thirteen years, during which nine different superintendents and a most miserable political ring, beginning with Tweed and ending with the asylum ring, essayed its management, it was changed to an insane asylum. During all these years it roused and educated public sentiment to recognize the disease of inebriety, and the need of asylum treatment. Its influence spread over all countries, and to day over a hundred asylums for inebriates are in active operation, all dating from the success of Binghamton Asylum. Here the fact was demonstrated that inebriety was a disease, and curable as other diseases are.

The continuation of Binghamton as an inebriate asylum was only a small matter compared with the establishment of a new fact and practical discovery in science. Binghamton Asylum was a success, far beyond any present political or selfish conceptions or any comparative estimates with other asylums. It has done what no other asylum has done in this country. It has proved the reality of a theory over a thousand years old and opened a new realm of practical science and pointed out a new road for humanitarian work. If every asylum at work to-day will do as much for the cause of science as the asylum at Binghamton has done we shall have a great forward movement and revolution of our present conceptions of mental disease.

Yours, etc.,

T. D. Crothers, M.D.

PATHOLOGICAL LANGUAGE.

To the Editor of the Medical Record.

Sir: In a recent number of the Medical Record there was an item headed "A Pathological Language." It may be of interest to some of your readers to learn that several such cases as therein mentioned have been under my care during the past ten years. The first were two brothers, six and seven, who spoke fluently a language of their own. Both gave the impression of having tongues too large for their mouths; properly exercised they became compact and agile, and correct articulation resulted.

The elder was strong and energetic but much slower than his brother in learning to speak well.

A girl of thirteen under my care at the same time possessed a like unwieldiness of tongue, which was overcome in about two months. Being of German parentage she had attempted to speak two languages and had succeeded in developing one of her own, possessing many sounds of English and German, but unintelligible.

Another case was a bright boy of twelve, who was unable to use in speech that part of the tongue between the tip and top, and had an over-activity of the back. In consequence he had made every s and z, a k or g. In sentences not possessing many hissing sounds it would be quite easy to understand him, as "It ig a pleagant day," but the question, "Is Augustus sick?" was changed to "Ig Auhugtug hick?" "I go to study sounds," became "I go to hudy hounk." Sister was pronounced higter.

Number five was a young man of twenty, who did not use the back of his tongue at all, or modify vowels with the lips. The effect was exaggerated baby talk and often it was impossible to understand him.

The most recent cases are two brothers aged six and a half and eight, who came under my care just a year ago. I took notes of their language in Bell's Visible Speech symbols, and will quote from my note-book.

"Ordinary words were given so strangely that an interpreter was needed. Often the parents and nurse could not understand their simplest wants. The elder developed a tendency to sign and gesticulate; the younger was becoming morbid and sensitive. They understood each other at all times, having perfected a language that met all their demands and supplied continuous conversation. When talking together their speech was too rapid to be written, but when asked they would repeat the sentences a number of times and always exactly."

The younger boy was the slower in gaining control of his vocal organs, being for some time unable to raise the point of his tongue to the upper gum. Their language did not have any pronouns, prepositions (except kŭ for and), or possessive case.

Examples.—Wee wah Ah-wah'-wee (Lexington Avenue). 'E waw Mā'-e-waw Ah-wah'-wee (We walked on Madison Avenue). Kah goo, kā kee goo (That is good,

very good). Goo pă koo (new pair of shoes). Kă-koo lū mū (Thank you very much). Ah kaw koo pāya (I like to play). Pee pāya (piece of bread). Wah (1), koo (2), kyee (3), paw (4), pah (5), kūya (6), kă-keeya (7), wāya (8), ngah (9), kā (10). Koo kaw kee kee (New York City). Pū-kă-kū (potato). Gaw bĕ (strawberries). Wă-kū pā gū (asphalt pavement). Ah gah-baw (I forgot).

These boys are unusually energetic and remarkably bright. After acquiring distinctness of speech it was found necessary, as in nearly all other cases, to teach them to arrange words in sentences, their mistakes in grammar being similar to those of a foreigner. None of them were under my instruction longer than a few months. The older ones are now self-sustaining. All recollection of their peculiar languages was lost as soon as ability to speak plainly was secured. They had evi dently heard the speech of those about them perfectly.

Perhaps my observations may be of interest to those studying such subjects and they may be able to explain if these conditions are due to some defect in the speech-centre (perhaps congenital?).

LILLIE E. WARREN.

243 WEST TWENTY-FIRST STREET, NEW YORK.
February 2, 1891.

PORK EATING AND CANCER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Not long ago a paragraph was quoted in the RECORD, saying that cancer was unknown among the Jews, and that this immunity was due to the fact that they eat no pork. With the first statement I can have no quarrel, but the deduction from it remains to be proved.

The Mohammedans abhor pork as religiously as do the Jews. In all the interior of Asia Minor the pig is an utterly unknown animal, except from hearsay. I suppose this is true of the greater part of Turkey, but I speak positively only of that part of the country with which I am acquainted. Yet, in spite of this absolute absence of pork, cancer is by no means an uncommon disease. I have seen carcinoma and sarcoma among Mohammedans as well as among others in Turkey. Though cancer may be more common among pork-eating peoples, yet it must also have causes other than those due to the eating of this meat.

WILLIAM S. DODD, M.D.

VIENNA, January 27, 1891.

SULPHATE OF CINCHONIDINE IN INTERMITTENT FEVER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the MEDICAL RECORD for October 11, 1890, there is an editorial on sulphate of cinchonidia, in which an abstract of Dr. H. de Brun's study of this alkaloid is made.

The results of Dr. de Brun's investigations are referred to as if they were something new. The facts are, however, the same as have been known for many years. I would call your attention to a paper on sulphate of cinchonidia, published by me in the *Medical and Surgical Reporter* for February 14, 1874, based upon the action of the alkaloid in seventeen cases of malarial fever. In six of these quinine had already been given without success.

In the above contribution I referred to the successful use of cinchonidia in 129 cases of intermittent fever by Dr. Cullen, in 1855, and also to the report of the Madras Commission in 1868.

There is a popular prejudice in favor of quinine, and when the price of this salt is so low as it is at present many use it in preference to any of the other cinchona alkaloids.

Cinchonidia is, however, fully equal to quinia as an antiperiodic, and has some advantages over the latter in being more soluble, less bitter, and less likely to cause disagreeable head symptoms. Moreover, it is successful in many cases in which quinine has failed.

I believe that sulphate of cinchonidia is now used largely in the South and Southwest.

Yours very truly,

WHARTEN SINKLER, M.D.

PHILADELPHIA, January 24, 1891.

FROM ANOTHER POINT OF VIEW.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the editorial columns of the RECORD of February 7, 1891, appeared the timely question, "Should a Poor Man Study Medicine?" The question is certainly one that invites reflection, and requires a thorough analysis of the condition and needs of the times as they bear upon the practice of medicine. The many, and increasing, free dispensaries in New York and other cities undoubtedly constitute grave obstruction to the progress and pecuniary welfare of young medical practitioners who depend upon civil practice in those cities for a living. But let us call attention to one fact that seems to have been overlooked. In the United States it is possible only for about seven millions of people to seek advice and treatment at free dispensaries. This is a liberal estimate, for it includes all the residents of those cities which contain free dispensaries.

Deducting this number from the total population leaves more than fifty-five millions of people to be treated by physicians, who need not be rich, but intelligent, honest, and competent.

To us it would seem unjust and unwise to make wealth a necessary qualification before a person can enter upon the study of medicine. Every one fully understands the magnitude of competition in a great city like New York, and anyone who feels himself unable to cope with this modern essential of city life, let him seek work in other localities.

I am, very truly, yours,

W. P. SPRATLING, M.D.

STATE ASYLUM FOR THE INSANE, MORRIS PLAINS, N. J.
February 11, 1891.

"RACIAL IMMUNITY AND INOCULATION."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the article under the above caption, by Albert S. Ashmead, in your issue for January 10, 1891, that author states that the Japanese enjoy immunity from scarlatina.

I wish to relate, in response, the history of a case which is now under my care. On January 19, 1891, I was called to see Mr. O. T——, aged twenty-two, of Tokio, Japan, who is at present a student at Cornell University. On the evening of January 18th he was taken with what he and his friends were pleased to call a bilious attack. He complained of a sore throat, and his temperature when I first saw him was 104° F., with accompanying severe prostration. The tonsils were ulcerated, and, to my surprise, there were decided evidences of scarlatina upon the roof of the mouth and the soft palate. Upon further examination of the body I found a complete eruption of scarlatina. The case, a sporadic one, was typical. Temperature at second visit 105° F., breath very offensive, and tongue much inflamed. In fact the case was more severe than any scarlatina case treated by me within the last eight years. The patient is at present convalescent, and desquamating extensively.

Having read the recent article of Dr. Ashmead it seems proper to record this case of scarlatina occurring in a native of Japan.

Yours very truly,

J. S. KIRKENDALL, M.D.

ITHACA, N. Y., February 1, 1891.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 8, 1891, to February 14, 1891.

MAUS, LOUIS M., Captain and Assistant Surgeon. By direction of the Secretary of War, is relieved from further duty at Fort Stanton, N. M., and will report in person to the commanding officer at Whipple Barracks, Arizona Ter., for duty at that station, relieving Captain Richard W. Johnson, Assistant Surgeon. S. O. 35, par. 7, A. G. O., Washington, D. C., February 12, 1891.

JOHNSON, RICHARD W., Captain and Assistant Surgeon. By direction of the Secretary of War, on being relieved by Captain Maus, will report in person to the commanding officer at San Carlos, Arizona Ter., for duty at that station. S. O. 35, par. 7, A. G. O., Washington, D. C., February 12, 1891.

JOHNSON, R. W., Assistant Surgeon. Granted leave of absence for one month, to take effect on or about February 10th instant. S. O. 16, par. 1, Department of Arizona, Los Angeles, Cal., February 4, 1891.

WOLVERTON, WILLIAM D., Major and Surgeon. Granted leave of absence for one month, to take effect on or about February 15, 1891. S. O. 15, par. 2, Department of the Platte, Omaha, Neb., February 7, 1891.

MERRILL, JAMES C., Captain and Assistant Surgeon. By direction of the Secretary of War, is relieved from duty at Fort Reno, Oklahoma Ter., and will report in person, at the earliest practicable date, to the Surgeon-General U. S. Army, in this city, for duty in his office. S. O. 29, par. 5, A. G. O., Washington, D. C., February 5, 1891.

Official List of Changes in the Medical Corps of the United States Navy for the week ending February 14, 1891.

AUZAL, E. W., Passed Assistant Surgeon. Detached from the Boston and ordered to the Lancaster.

CRAIG, T. C., Passed Assistant Surgeon. Detached from the Vesuvius and ordered to the Boston.

BRAISTED, W. C., Assistant Surgeon. Detached from Hospital, Hot Springs, and ordered to the Vesuvius.

FITTS, H. B., Passed Assistant Surgeon. Ordered to the Army and Navy Hospital, Hot Springs.

ARNOLD, W. F., Assistant Surgeon. Ordered to the Receiving-ship Vermont.

BLACKWOOD, N. J., Assistant Surgeon. Detached from the Vermont and ordered to the Newark.

ASHBRIDGE, RICHARD, Passed Assistant Surgeon. Ordered to the Navy Yard, New York.

NORTH, J. H., Assistant Surgeon. Detached from the Navy Yard, New York, and ordered to the Lancaster.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 14, 1891.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	12	5
Scarlet fever	178	26
Cerebro-spinal meningitis	3	3
Measles	462	19
Diphtheria	106	34
Small-pox	1	0
Varicella	9	0
Pertussis	1	0
Croup	2	0

Association of American Anatomists.—The third annual meeting was held at Boston, Mass., December 29 and 30, 1890, in the anatomical lecture-room of the Harvard Medical School. It was presided over by Dr. F. D. Weisse, second vice-president, and Dr. Thomas Dwight acted as secretary *pro tem.* Papers were read as follows: "Corrosion Preparations," by Dr. S. J. Mixter; "Studies on the Spine," by Dr. Dwight; "A Comparison of the Fibrin Filaments of Blood-lymph in Mammalia and Amphibia," by Professor S. H. Gage; "The Semilunar Bone," by Professor Shepherd; "The Structure of Protoplasm and Mitosis," by Dr. Carl Heitzmann; "The Homology of the Cerebro-spinal Arachnoid with the other Serous Membranes," by Professor Langdon; "The Occlusion of the Rhinocœle (Olfactory Ventricle) in the Dog," by Mr. P. A. Fish; and by Professor B. G. Wilder, "The Relation of the Olfactory to the Cerebral Portion of the Brain;" "The Brains of a Cat and of a Sheep Lacking the Callosum;" "Owen's Nomenclature of the Brain, with Suggestions Based thereon." With one exception the papers were illustrated by specimens, photographs, or diagrams, and all were fully discussed. The Committee on Anatomical Nomenclature, Professors Leidy, Harrison Allen, Frank Baker, Thomas Dwight, T. B. Stowell, and B. G. Wilder, were authorized to publish as their second report "such general and specific recommendations as may be unanimously agreed upon by them." The following were elected members: Dr. W. L. Dana, of Portland, Me.; Dr. John C. Munro, of Boston, Mass.; Mr. Pierre A. Fish, of Ithaca, N. Y. The next meeting will be held at Washington, D. C., at or about the time of meeting of the Congress of American Physicians and Surgeons, in September, 1891. The officers for that meeting are as follows: *President*—Dr. Joseph Leidy; *Vice-Presidents*—Drs. Frank Baker and F. D. Weisse; *Secretary and Treasurer*—Dr. D. S. Lamb; *Executive Committee*—Drs. Harrison Allen, Thomas Dwight, and B. G. Wilder.

Is "Parataloid" of Uniform Strength?—Dr. Andrew H. Smith writes, February 6, 1891: A recent experience leads to the question whether different specimens of Koch's fluid have necessarily the same strength. A patient at the Presbyterian Hospital, having pulmonary phthisis, was inoculated with gradually increasing doses until, at the tenth inoculation, $3\frac{3}{4}$ milligr. were employed. The reaction from this dose, as from all the preceding doses, was objectively almost nil, although subjectively there was slight malaise. Improvement in the physical signs was noted after five or six inoculations. The eleventh inoculation consisted of $4\frac{1}{2}$ milligr., and was made with a new specimen of parataloid just received from Berlin. The reaction began eight hours afterward, and attained its maximum in four hours. It was excessive, not to say alarming. The temperature reached $104\frac{1}{2}$° F., and the pulse 150. The whole chest was filled with moist râles; there were cyanosis and drowsiness. In the course of four hours more the temperature had declined to 102° F., and from that point it gradually sank to normal. The râles persisted for twenty-four hours longer, and then disappeared. The case was one of incipient phthisis, with indistinct physical signs, and with no elevation of temperature, and but for the presence of bacilli the diagnosis would have been doubtful. The lymph first employed produced the usual reaction in other patients. Inasmuch as the active principle of the lymph is the product of a vital process of which there can be no definite measure, it is hard to see how the conditions under which it is produced can be known to be uniform. Not being a definite chemical substance, parataloid cannot be subjected to quantitative analysis. It seems, therefore, that its strength can be determined only by experiment, and that great care will be required in changing from one specimen to another.

Will Explode if Mixed.—"Chemicus" writes that the solution of permanganate of potash and glycerine recommended by Dr. Dupon for the bites of venomous insects,

in a recent issue of the RECORD, is an impossible one, judging from his experience, and its attempted preparation dangerous. When glycerine is added to permanganate, deflagration ensues, and if the permanganate be gradually added to the glycerine, while solution may be quietly effected the decomposition is almost equally prompt. I would suggest that your readers be warned.

A New Table of Atomic Weights.—By request of the Committee of Revision and Publication of the Pharmacopœia of the United States, Professor F. W. Clarke, Chief Chemist of the United States Geological Survey, has furnished a table of atomic weights revised upon the basis of the most recent data and his latest computations. This table has been published and distributed, with the request that all calculations and analytical data which are to be given in reports or contributions intended for the use or cognizance of the Committee be based upon these values. The Committee in its pamphlet also suggests that it would be highly desirable that the table be adopted and uniformly followed by chemists in general, at least for practical purposes, until it is superseded by a revised edition. The recommendation is a wise one and deserves wide acceptance. Not that a difference of a fraction in the atomic weights of an element would materially affect the composition of a medicinal compound, but it is for the sake of unity that the table should be generally adopted. Chemistry is an exact science, and for chemists to be working with different valuations for the same element is confusing, and a sacrifice of uniformity and exactness that can and should be prevented. If all architects should follow their own ideas with no regard to the axioms of the science, a city could doubtless be built, but, to say the least, it would be picturesque. Likewise chemists can continue working with the atomic weights to which they are accustomed, but results would be much more satisfactory and uniform if a general standard were adopted. All calculations in reports to the Committee of Revision of the Pharmacopœia must be based on Professor Clark's table, or the committee will be compelled to revise the entire work. That the valuations of Professor Clark are deserving of acceptance goes with the saying, as he is one of the greatest of authorities, and has at his command every necessity and convenience for the work. We append that portion of the table which includes officinal elements :

Name.	Symbol.	Atomic Weight.	Name.	Symbol.	Atomic Weight.
Aluminium	Al	27.	Iron	Fe	56.
Antimony	Sb	120.	Lead	Pb	206.95
Arsenic	As	75.	Lithium	Li	7 02
Barium	Ba	137.	Magnesium	Mg	24.3
Bismuth	Bi	208.9	Manganese	Mn	55.
Boron	B	11.	Mercury	Hg	200.
Bromine	Br	79.95	Nitrogen	N	14.03
Calcium	Ca	40.	Oxygen	O	16.
Carbon	C	12.	Phosphorus	P	31.
Cerium	Ce	140.2	Potassium	K	39 11
Chlorine	Cl	35.45	Silicon	Si	28.4
Chromium	Cr	52.1	Silver	Ag	107.92
Copper	Cu	63.4	Sodium	Na	23.05
Gold	Au	197.3	Sulphur	S	32.06
Hydrogen	H	1.007	Zinc	Zn	65.3
Iodine	I	126.85			

Quill Drainage-Tubes.—Dr. Otis K. Newell, of Boston, Mass., writes: "In reply to one of your readers, would say, and should have said in my account of Dr. Beach's quill drainage tubes, that they are punched after soaking some hours in 1 to 20 carbolic acid solution."

How to Keep the Paquelin Cautery in Good Order. It is claimed that Paquelin's cautery would never be found out of order if the following instructions, given by M. Colin, were followed strictly: The benzine employed should be of from 700° to 720°, using the petroleum densimeter, at a temperature of 59° F., that is to say, it should weigh from 700 to 720 gm. to the litre. At most, it should not occupy more than a third of the capacity of the reservoir. In case of need, the hand-bulb may be replaced by a pair of bellows. During the whole operation, the temperature of the benzine should be kept at from 59° to 68° F., to accomplish which it is only necessary to hold the reservoir in the hand or carry it in one's pocket. Too high a temperature hinders the incandescence of the cautery. The platinum point should be placed in the lateral portion of the flame, at the level of the centre. Use pure alcohol for the lamp. Avoid heating the platinum to the luminous point. If the cautery cools off, work the bulb vigorously, and if necessary place the point in the flame again. When the operation is finished, before allowing the cautery to become extinguished, bring it to a bright red by a few rapid insufflations, and then, while it is fully incandescent, detach the rubber tube from the handle suddenly. Let the cautery cool in the open air. Cleanse it with a moistened rag. If the instrument is not used very often, it is well to heat the various points from time to time.—*New York Medical Journal.*

African Arrow Poison.—The poisons used by the natives of Africa to render fatal the wounds made with their arrows, as described by Mr. Stanley in his recent work on Africa, are, when fresh, of most extraordinary power. Faintness, palpitation of the heart, nausea, pallor, and beads of perspiration break out over the body with extraordinary promptness and death ensues. One man is said to have died within one minute from a mere pin-hole puncture in the right arm and right breast; another man died within an hour and a quarter after being shot; a woman died during the time that she was carried a distance of a hundred paces; others in varying spaces of time up to a hundred hours. The activity of the poison seemed to depend on its freshness. The treatment adopted was to administer an emetic, to suck the wound, syringe it, and inject a strong solution of carbonate of ammonia. This carbonate of ammonia injection seems to have proved a wonderful antidote if it could be administered promptly enough. One of the poisons with which the weapons are smeared is a dark substance like pitch. According to the native women, it is prepared from a local species of arum. Its smell when fresh recalls the old blister plaster. It is strong enough to kill elephants. This poison is not permitted to be prepared in the village. It is manufactured and smeared on the arrows in the bush. These results of the African arrow poison are quite remarkable; but it would be interesting to know if they owe anything to fear and its effects, or if similar results can be obtained by inoculating the lower animals.—*Medical and Surgical Reporter.*

Bacillary Partnerships.—In the course of some experimental investigations on the relationship of micro-organisms with diseased conditions Drs. Cornil and Babès have discovered that a certain affinity exists between particular species. In other words, the development of special varieties may be facilitated, or the reverse, by the presence or pre-existence of certain other varieties. In this way the occasional complication of an existing infectious disease by a second is not the result of mere chance, but is governed by some still undefined conditions of environment. In other instances this association of two or more species of micro-organisms is necessary to the evolution of the malady. This association is the rule in the infectious diseases of human beings, and it is often the secondary infection that determines the fatal issue. This partnership arrangement may take place between microbes belonging to more or less nearly related species, as is the case with the organisms of pneumonia and typhoid fever. Or there may be streptococci and bacilli together, as in diphtheria, or several varieties of streptococci, as in the infection of wounds. In fact, there is a large selection of these associations, some invariable, others frequent, and a third category, in which the secondary infection is accidental. These facts may possibly throw some light on the rhythm and sequence of the symptoms in the infectious diseases.—*The Medical Press.*

INOCULATIONS WITH PROFESSOR KOCH'S "TUBERCULIN."[1]

By A. JACOBI, M.D.,

LATE PRESIDENT OF THE NEW YORK ACADEMY OF MEDICINE, CLINICAL PROFESSOR IN THE COLLEGE OF PHYSICIANS AND SURGEONS, ETC.

INOCULATIONS were commenced by me December 10th in the Mount Sinai Hospital, on the very day when Dr. Kinnicutt made his first injections in St. Luke's. On the following day I began in the German, two days after, at the suggestion of Dr. Reid, attending physician, in the Foundling Hospital. At a later period a case of epithelioma was observed, and inoculated for a while in the Skin and Cancer Hospital. The majority of the cases in the Mount Sinai Hospital belonged to the service of Dr. I. N. Heinemann, attending physician, a number were also furnished by the other physicians and surgeons of the institution, and some of the most interesting material by Dr. Goldenberg. To Dr. Heinemann belongs the credit of having spent a great deal of time and labor on the numerous cases gathered in that institution, while I attended the other places. He will appear before you with the reports of what he has observed and accomplished. The cases which form the basis of my report number about sixty, fifty of which were observed in the German Hospital and I are carefully tabulated. They comprise nearly all the varieties of tuberculosis, that of meninges, lungs, glands, bones, peritoneum, joints, every one of which was carefully watched by a most competent house-staff and painstaking nurses both day and night, and temperatures taken, with rare exceptions in rectum or vagina, almost in every case every two or three hours for weeks in succession. I may be permitted to add a single remark, viz., that from the beginning I have tried to be as unbiassed in my observations and experiments as would be permitted by the overpowering sense of the influence of a scientific discovery of extraordinary weight and importance.

The effects claimed by Robert Koch for his "Tuberculin" are as follows:

Its action on tubercular processes of whatever nature, is specific. It is either general or local. Reaction in internal organs cannot always be proven, because it is not amenable to direct observation, with the exception of increased cough and expectoration; here the general reaction predominates. There are local changes in the visible tubercular processes. An injection of 1 ctgr. always has that effect. Therefore, the lymph is an indispensable means of diagnosis. When the diagnosis of tuberculosis cannot be obtained by the finding of bacilli or elastic fibres in the sputa, tuberculosis can with safety still be diagnosticated by the presence of the reaction. In the same way doubtful cases of glandular, osseous, and cutaneous disease can be recognized.

The action of the lymph on the tissue surrounding the bacillus is marked. It produces changes resulting in necrosis of that tissue without destroying the bacilli. In the beginning small doses are sufficient, afterward larger ones are required. When a tuberculous patient requires as large doses as a healthy person, at the same time exhibiting as little reaction as the latter, it is to be presumed that all the tuberculous tissue amenable to reaction has been destroyed.

Phthisical patients in the first—incipient—stage were relieved of all morbid symptoms in from four to six weeks, so that they could be considered as cured.

Patients with cavities of moderate size were much improved and almost cured. Thus it is to be presumed that incipient phthisis can certainly be cured through this remedy. Relapses are possible, for the time of observation has been too short. Still it is fair to presume that relapses will be removed as quickly as the first attack.

The general reaction means increase in temperature. It seldom appeared after an hour or two, generally after from four to nine hours, reached its maximum mostly about the ninth or twelfth hour, and diminished gradually. Sometimes after it had commenced to sink it had another rise, as you will remember to have seen in many of your cases of typhoid fever, where a double curve is not unusual. In a number of my children the temperature rise was not marked. Proportionately large doses were required. There is a parallel, perhaps, with what we notice in other circumstances. For instance, cardiac stimulants require larger doses, comparatively, in children, and in them also the effect of the typhoid infection is less marked. Both the typhoid virus and the Koch virus are ptomaines. Still this is but a suggestion.

The general reaction was noticed in many cases after doses of 1 or 2 milligr. That effect was not obtained when, after a brief time, ten or twenty times as much was injected.

The increase of temperature would often correspond with pulse and respiration; sometimes these two would not, or not much, be affected. The general condition of the patient would mostly be altered with the change of temperature, but not always in the same proportion. Sometimes there was comfort with high temperature, sometimes great discomfort, languor, muscular pain; once a localized pain in a distant organ (the left arm) when the right elbow was affected, rigor, perspiration, with a moderate temperature; in one case (with no rise of temperature) there ensued very great dyspnœa, angina pectoris, fear of annihilation, which required active medicinal interference.

Instead of rising after the inoculations, the temperature may fall, but the patient's comfort may increase. At the same time, with a low temperature, and feeling comfortable, he may improve, or not improve, or get worse. The temperature may also fall, but the patient, while getting worse, may also feel worse.

In cases of non tubercular lungs (suspicious or not) the temperature may rise, or no. In those of tubercular lungs I have seen inoculation raise the temperature, not influence the temperature, and reduce the temperature. The changes in the lungs were not uniform. The usual results of an inoculation were diffuse rhonchi, sometimes dyspnœa, and increased expectoration, which became more mucous, and was a few times tinged with blood. Thus it happened that in one case the number of râles and of indurated areas increased in number and extent; sometimes with dangerous, either temporary or persistent results. Sometimes this effect remained more or less stationary, sometimes it wore off in a day or two. In other cases there were no direct local changes, and still there was an improvement of both subjective and objec-

[1] Read before the Medical Society of the State of New York, February 4, 1891.

tive symptoms. The absence of bacilli in the sputum does not speak against the tubercular nature of the case as long as the time of observation is but a few weeks.

Respiration was often accelerated and superficial, but seldom more than in its due proportion to the increase of temperature. Anorexia and nausea were frequent, vomiting not uncommon. Jaundice I have not seen, with the exception of a very slight touch in a single case; a few times I met with small quantities of albumin in the urine, mainly during high temperatures.

In a small number of cases, mainly such as had a high temperature, the spleen would swell and sometimes be painful, on the second day or later. Another symptom of ptomaine infection was the peculiar appearance of the tongue, accumulations of epithelium in the middle, elevation and redness of papillæ, intense raspberry or scarlet redness of the edges.

Local reaction was sometimes observed round the site of injection; in many cases there was no pain, in others there was. In a minority there was some local redness, in a few some swelling, a day after the inoculation. The eruption was in one case of the size of a hand. A general eruption I have seen but once, when, three days after the first inoculation was made (this time of 1½ milligr.), almost the whole body of the child was covered with a papular rash; afterward 10 milligr. were injected without any such result. Another form of local reaction is that observed near the tubercular locality. It consists in local congestion, redness, swelling, sensibility of the affected parts, be it lupus, gland, sinus, or bone; or such changes in the pulmonary tissue as have been alluded to. It must be said, though, that this may also take place in tissues not affected by tuberculosis.

For the purpose of diagnosis lymph was injected into Louisa K—— , aged twenty. She was admitted November 14th, with the diagnosis of peritonitis, probably carcinomatous. There being a strong doubt expressed because of the youth of the patient and for other reasons, lymph was injected on four successive days—2 milligr., 4 milligr., 5 milligr., 5 milligr. No reaction. The larger number of such administrations in tuberculosis proving successful in producing a reaction, the diagnosis of carcinoma was considered justified.

Maria T—— , aged twenty, admitted January 17th. Had a cough since last summer with moderate expectoration. sometimes with a little blood, and some dyspnœa. Ten days ago a chill, pain in her throat; stopped work four days ago; has a "cold," coughs considerably, bled from the nose once. Had no fever when admitted. Over right upper lobe anteriorly, dulness and coarse respiration, some bronchophony. Posteriorly, prolonged respiration. Bacilli not found. On three successive days, 2, 4, and 6 milligr. were injected without any effect. Meanwhile she improved while in bed. The physical lung symptoms are probably due to the results of an interstitial pneumonia in early life.

Lena K——, aged nineteen, admitted December 31st, with symptoms of gastritis, and coarse respiration, with moderate dulness over right upper lobe both anteriorly and posteriorly. No response to 2 milligr. Probably the same conditions as in the previous case.

Kate S——, aged twenty-three, admitted November 22d, with fibrinous pneumonia and pleuritis of the left side. When, about the middle of December, resolution was not complete, dulness and some cough, also rhonchi, persisting, the suspicion of the presence of tuberculosis induced me to use the lymph. Very soon bacilli were found. From December 16th to 23d she received five injections of from 1 to 4 milligr. Reactions were quite marked, and she felt badly. Therefore the treatment was interrupted ten days, and resumed with occasional doses of 5 or 6 milligr. Since January 22d she is on daily doses of 3 milligr., during which she had less fever than before and feels better. Still the physical examination of her left lung and pleura is unsatisfactory; particularly as when there was a considerable reaction the whole chest was full of crepitant, subcrepitant, and sibilant râles. Indeed, she is one of the cases which appear to respond so thoroughly, locally, that the fear is justified that the congestion of the pulmonary tissue resulting from the injection may prove dangerous.

Max H——, aged four, admitted January 18, 1891; service of Dr. Kammerer. Scrofulous dermatitis of face. About the ascending ramus of maxilla, left side, the skin is red, indurated, and partly ulcerating and proliferating. Internal organs healthy. For the purpose of diagnosis some inoculations were made, twice of ½ milligr., once of 1, and once of 2 milligr. The latter dose raised the temperature to 102.6° F. within twelve hours, but there was no local reaction, and the inoculations were discontinued.

Conrad S——, aged forty-six, admitted November 11th. Tumor in larynx and ulcerations. Dulness over right lung, rhonchi, no bacilli found in repeated examinations. Deglutition and articulation difficult. Had chancre twenty-eight years ago. Iodide of potassium and inunctions proving rather inefficient, he was given the benefit of the doubt, and three injections were made on January 16th, 17th, and 18th, of 2, 5, and 7 milligr. As no reaction became visible, the anti-syphilitic treatment was resumed.

Ernst S——, aged forty-two, admitted January 2, 1891, with temperature 101.1° F., has a small ulceration on the right side of epiglottis, with some surrounding infiltration. One cervical gland. The diagnosis of syphilis very probable, but as there was a dull area over the right apex, he was given the benefit of the doubt. Injections were made

January 2d. Two milligr. After six hours temperature fell to 99.5° F.

January 4th. Four milligr. No reaction, except, perhaps, the temperature of 101° F., which he had before, thus the anti-syphilitic treatment was commenced in earnest.

P——, grocery boy, aged fifteen, admitted January 12th, to Dr. Kremer's service. Dermatitis genu chronica. Scrofula in childhood. Popliteal gland removed six months ago. Since an indurated area in the popliteal region six inches in length. Internal organs negative. For the purposes of diagnosis four inoculations were made on January 13th, 16th, 17th, and 18th, of 1, 2, 4, and 6 milligr., without any reaction. The probability was that the dermatitis is not tuberculous, a piece of the skin was then removed for examination, and no bacilli found.

Caroline L——, domestic, aged thirty-six. Had the last of several pneumonias in February, 1889, frequent attacks of dyspnœa and catarrh since, and moderate cough. Some phthisis in the family. On December 21st, beside a number of gastric symptoms of which she complained, she had extensive dulness and diminished respiration on the right side, the seat of her last pleuro-pneumonia.

One milligramme of lymph was injected at noon, December 20th. Pulse rose from 90 to 100 at 2 P.M.; temperature from 98.6° to 100° F., at 8 P.M. It remained at from 100° to 101.2° F., until next noon, when 2 milligr., were injected. It did not influence the temperature, which remained about the same (100° to 101.2° F.) until noon December 22d. The first two nights, however, she coughed more than usual, had dyspnœa, palpitation, and perspiration, also dizziness and headache. She expressed the same complaints the following days, lymph or no lymph, while her average temperature was less. Only once, on December 23d, it rose to 100.4° F., also on December 24th, at 5 P.M. Then 3 milligr. were injected at 7 P.M. Ten hours afterward, at 5 A.M., December 25th, temperature 98.6° F., at 8 A.M., 101°, the highest temperature of the day except 101.4° F., at 8 P.M. Temperatures up to 101° F. were observed on December 26th; 100.8° F., also at 8 A.M., December 27th. After that time until January 5th, when she left the hospital, the temperature was normal, though she complained of alleged chills, headaches, back-aches, stomach-aches. After all we can say

that as the lymph had a negative result, both generally and locally, the changes in the lungs were not likely to have assumed a tubercular character—provided that the majority of lymph results are of the diagnostic importance attributed to them by Robert Koch.

A. W——, aged fifty six, musician, admitted December 20th. Complained these three months. Has anorexia, ascites, icteric complexion, is feeble. Urine scanty. No history of alcoholism. On examination: Temperature, 99.8° F.; pulse, 120, very feeble. Urine with trace of albumin. Heart negative. Over left lung, superiorly, dulness and coarse breathing. Ascites with but moderate sensitiveness. Iodide of potassium, 2 gm. daily. Paracentesis with permanent drainage; 2,000 gm. on December 25th, 3,000 on the 26th, and 500 on the 29th. On the last two days the fluid was less clear, and contained blood and pus-cells. He was gradually sinking; no good, no harm could be done. One milligr. of Koch's lymph was injected December 31st, at 7.50 P.M., while his rectal temperature was 97.5° F. No reaction of any kind; he continued to sink until January 1st, when he died at noon. No autopsy permitted.

Betty S——, aged thirty, admitted November 22, 1890, six weeks after her sixth confinement, for general debility, dyspnœa, abdominal and dorsal pain, leucorrhœa, pelvic symptoms. Uterus large and catarrhal. Dulness over right lung, anteriorly, and coarse and prolonged expiration. For the purpose of diagnosis 1 milligr. of lymph was injected December 28th, with no increase of temperature, but marked perspiration. On the evening of January 14th, 2 milligr. were injected, temperature being as always, 98.6° F. Within seven hours, at 2 A.M., it rose to 100.6° F., and had commenced to fall at 5 A.M., when it was 99.6° F. Left the hospital.

Robert N——, aged forty-four, working man, admitted November 29, 1890. Complained of his stomach these fourteen years. For three weeks vomiting, mucous expectoration, and cough. Had chills and pleuritic pain, and lost flesh. Has some dulness over upper lobe, superiorly, and sibilant and mucous râles during inspiration and expiration. No pus, no bacilli. Had temperatures in the first ten days, on December 8th, 103° F., but only once, after that temperature, mostly normal, some few times 101.2° F. On the afternoon of December 16th temperature rose once to 102.8° F., and again on the 17th. For the purpose of diagnosis, 1 milligr. of lymph was injected on the evening of the 17th. For twenty-four hours subsequently the temperature changed between 101.2° and 102.5° F., then it rose to 103.2° and 104.2° F., about twenty-four hours after the inoculation. There were more rhonchi, this time over the whole chest; more dyspnœa. Death occurred on the 19th. No autopsy permitted; perhaps the question might have been settled whether through our congesting and softening the tissue which surrounded the nests of bacilli we hastened the man's death. For though no bacilli were found, I have no doubt it was a case of tuberculosis.

Rosa J——, aged thirteen, had undergone an operation for swollen cervical glands on the right side. Left in September apparently in good health. Admitted December 31st, because of general indisposition and fever. At the upper end of the cicatrix a glandular swelling. Over the right upper lobe diminished respiration behind, and some dulness both anteriorly and posteriorly. A few days in bed restored her temperature almost to the normal. After the evening of January 4th the temperature never rose. For the sake of diagnosis lymph was injected. One milligr. on the morning of the 3d; 2 milligr. on the evening of the 4th; 5 milligr. on the evening of the 6th; 10 milligr. on the evening of the 7th; with not a trace of response. Inoculation was stopped. We also learned from Dr. Kammerer, who performed the operation in July, that the glands he removed were not considered tuberculous. This case would then be conclusive of the motto: "No tuberculosis, no reaction."

A number of cases of external ("surgical") tuberculosis, with two of epithelioma which were introduced as probable cases of lupus, are as follows:

A boy, aged four, with tuberculosis of right knee, tubercular glands of neck, and infiltration of right apex; also an abscess of the right thigh in which bacilli were found. Inoculations were made, twelve in number, ranging from one-half to ten milligrammes. There was some slight response to the first, induced rather more by the first small injections than by the later ones, which were large. No correspondence between such response as was elicited by the lymph in the beginning and the pulse and respiration. This correspondence was more distinct on the last two days of the observation when no inoculations were made; but then the fever was considered the result rather of the suppurating thigh than of the lymph. The final dose of 10 milligr. was rather a large one, but no reaction distinctly attributable to it made its appearance. No change.

Harry C——, aged five years eight months, with tubercular abscess (bacilli found) in right inguinal region, presumably from lesions of lumbar vertebræ. Examination of viscera negative. The first inoculation of half a milligramme resulted in a distinct reaction, which showed itself in a rise of temperature and of respiration, not of the pulse. Afterward the reactions were but trifling, or negative, even with a dose of 10 milligr. No improvement.

E——, aged four years eleven months, tubercular disease of left hip; discharging sinus. Examination of viscera negative. Fourteen inoculations between December 13th and January 3d, from one-half to ten milligrammes. The first small inoculations resulted in positive reactions, the temperature rising to nearly 104° F.; the last large ones in none, or none attributable to the remedy. No improvement.

W. C——, aged four years nine months; dorsal spondylitis; kyphosis. Lungs negative. No bacilli were found, and therefore no tuberculosis could be proven. There was, however, a pretty smart double reaction after the first injection of half a milligramme. Very little reaction took place after the subsequent doses, from one to ten milligrammes. Cervical glands became tumefied. Induration and moderate redness of the injection site appeared a day after inoculation in this and the preceding three cases. Reaction, such as it was, took place in from four to fourteen hours. The pulse was more influenced than respiration.

I. T——, aged four years and a half. Cold abscess, probably from right sacro-iliac synchondrosis. Heart and lungs normal. Operations on September 26th and October 13th. Afterward the general condition good. No temperatures. Wound almost healed on December 1st, but his condition remaining stationary for some time, ten inoculations were made between December 13th and 30th, gradually rising from 1 to 5 milligr. On January 1st the examination of the boy showed condition generally good, the wound, however, but slightly improved. The first injection of 1 milligr. showed the most marked results; reactions occurred in from ten to twenty-two hours, and grew less and less unless the doses were increased.[1]

Auguste M——, aged three. Tuberculosis of left tibio-tarsal articulation. Removal of sequestrum, etc., in September, after that temperature normal, moderate suppuration of fistula, swelling of inguinal glands.

December 11th, one milligr. at 4.45 P.M. After midnight temperature 102°, 102.5°, 102.8° F. As the temperature was still high on the twelfth, I injected only three-fourths milligr. Temperature rose in a few hours to 103.5° F., child somnolent, perspiring. Perspiration continued all night, though temperature was gradually falling.

On December 13th temperature only 100.8° F., less suppuration, no pain. Injected 1½ milligr.

[1] A detailed account of these five cases will be published in the Archives of Pediatrics, March, 1891.

December 14th. Child feels well, suppuration trifling. Temperature, 101.2° F.

December 15th. Injected 1 milligr. Sinus is closing.

December 16th. Injected 2 milligr. Perspiration; rhinitis.

December 18th. Injected 3 milligr. No symptoms.

December 20th. Injected 3 milligr. Temperature rose to 103.8° F., and remained above the normal all next day.

December 22d. Injected 4 milligr. Temperature, 101.4° F.

On December 24th, 26th, 28th, 30th, and January 2d, injections of 5 milligr. each, with but slight elevation of temperature and improvement in the local symptoms. Within a week after the doses were increased, with but slight increase of temperature, until on January 13th and 16th 10, and on the 17th 15 milligr. were injected without a rise of temperature. Four days afterward the child had a temperature of 101° F., a flushed face and a rapid pulse, without any assignable cause, unless it be a retarded effect of the inoculation. On January 27th the fistula greatly improved, not so deep as before, and with less secretion, still not entirely closed. The child in a fair condition.

Elise W— , aged eleven. Cutaneous tuberculosis, admitted December 18th. Family is tuberculous. Child had eczema. Underwent an operation at elbow-joint five years ago. Has an ulceration of the size of a silver dollar on the right side of neck, also one two inches long on chest; lungs normal. Inoculations the only treatment.

December 18th. Injection of 1 milligr. Highest temperature, 101.2° F. Itching on ulcerations.

December 20th. Injection of 1 milligr. 101.2° F.

December 21st. Injection of 1 milligr. Temperature normal.

December 22d. Injection of 2 milligr. Highest temperature, 102.3° F. Epistaxis and headache.

December 25th. Injection of 3 milligr. Temperature, 102.8° F.

December 26th. Injection of 3 milligr. No reaction.

December 27th. Injection of 3 milligr. Highest temperature, 102.6° F. Epistaxis, headache, palpitation.

December 29th. Injection of 5 milligr. Temperature, 100.6° F. Mild collapse. Subcutaneous injection of camphor.

December 31st. Injection of 6 milligr. No reaction.

January 3d. Injection of 6 milligr. Highest temperature, 101.1° F.

January 4th. Injection of 6 milligr. Little reaction.

January 6th. Injection of 6 milligr. No reaction.

January 7th. Injection of 8 milligr. No fever. Epistaxis. Headache.

January 9th. Injection of 10 milligr. No reaction.

January 13th. Injection of 10 milligr. No reaction.

January 16th. Injection of 10 milligr. No reaction.

January 17th. Injection of 15 milligr. No fever. Epistaxis.

January 27th. Injection of 10 milligr. No reaction. On this day the ulcerations were much improved, but not altogether well.

Annie T——, aged nineteen, housewife, admitted December 13th. Diagnosis: tuberculosis of right knee. Swelling began a year ago; also treatment, with variable results. Father died of consumption. All organs normal.

December 13th. Injection of one milligramme. Pain in the affected knee extending to hip; otherwise no change. On the 14th, swelling and fluctuation appear less.

December 14th. Injection of 4 milligr. Slight pain and redness and swelling at point of inoculation. After seventeen hours temperature, 101.2° F.

December 15th. Injection of 4 milligr. On the 16th highest temperature, 100.3° F. No other symptoms.

December 17th. Injection of 5 milligr. Next day temperature, 100° to 100.3° F. during twelve hours.

December 19th. Injection of 6 milligr. After twelve hours, temperature, 100.1° F.

December 20th. Injection of 8 milligr. After four hours, temperature, 101.4° F.

December 22d. Injection of 10 milligr.

December 30th. Injection of 10 milligr., with a temperature of 100.4° F. twenty-one hours after inoculation.

By some mistake the impression was gained that no reaction had taken place after the several doses, and inoculations were discontinued. They were renewed only after some weeks, when the true state of affairs was found out. At that time the apices also seem suspicious. No improvement.

Daniel D——, aged forty-two, admitted December 12th. Tuberculosis of right elbow-joint. Slight dulness over apices. Eight inoculations were made, of from one to five milligrammes in the course of a month, besides two surgical operations on December 16th and January 7th. The reactions after the injections were very marked, particularly after the first three or four, but the general condition and the total trouble of the patient leave much to be desired.

A——, working-man, forty-three years of age; admitted December 31st. Underwent a resection because of tuberculosis of ankle-joint years ago, with complete recovery. Suppurating fistule in the cicatrix this last month, an inch and a half deep, terminating in carious bone. Over right upper lobe, anteriorly, slight dulness and slightly bronchial respiration.

January 6th. Injection of 1 milligr. Temperature normal; pain in joint; headache, dizziness; appetite impaired.

January 11th. Injection of 2 milligr. Temperature, 102.6° F. Severe headache; palpitation; oppression.

January 13th. Injection of 2 milligr. Temperature, 101.4° F., twenty four hours after injection.

January 16th. Injection of 3 milligr. Temperature, 103° F. Palpitation, headache; feels "as if he were going to die."

Refused to be inoculated. An operation on diseased joint. General condition good.

Elise S——, aged sixty two. Admitted December 19th. Knee swollen a year ago, is painful and stiff; some cough; some dulness over right upper lobe; universal rhonchi. Temperature, 101.4° F.; pulse, 110.

December 22d. Injection of 2 milligr. After twelve hours, temperature, 103.1° F.; begins to fall six hours after.

December 23d. Injection of 3 milligr. After sixteen hours, temperature, 102° F. Pain in knee.

December 25th. Injection of 3 milligr. No change.

December 28th. Injection of 3 milligr. Temperature, 101.3° F.

December 29th. Incisions into the joint on either side; removal of tubercular granulations. Drainage and iodoform; ether. Purulent secretion from vagina; pain in abdomen.

December 31st. Injection of 6 milligr. The usual increase of temperature.

January 4th. Injection of 6 milligr. After sixteen hours, temperature, 104.2° F.; pulse, 122. Pain; some cough.

January 10th. New operation. More removal of granulations. Fever, dry tongue, intermittent and frequent pulse. Fever and increasing debility; pulse weaker; some cough the following days. Dies January 17th.

Autopsy: Tuberculous knee-joint; large abscess of fifth left rib; general miliary tuberculosis of lungs, liver, and spleen.

Ida S——, aged sixteen, caries of vertebræ and ribs. Admitted October 2, 1890. Was well up to two weeks before her admission, with the exception of general discomfort, debility, and emaciation, which had lasted five or six months. Family history, heart, lungs, and kidneys negative. She was treated with incisions, scraping

of the carious rib, injections of Thiersch's solution and iodoform in oil. Temperature ranged from 99° to 104° F.; pulse, 90 to 135. Her general condition improved gradually.

First inoculation of 1 milligr. on December 11th, while temperature was 102.2° F. Next morning temperature, 99.3° F., with pulse and respiration diminished accordingly, and less pus.

December 12th. Injection of 2 milligr. Temperature, 100.4° F., some perspiration; some cough. After sixteen hours, temperature, 99.3° F.; pus much less. After sixteen hours, temperature, 98.7° F.

December 13th. Injection of 3 milligr. Old sites of injections congested and painful. Feels well. Pale face. Next day more pus. Feels improved.

December 14th. Injection of 3 milligr.

December 15th and 16th. Injections of 4 milligr. Secretion less.

December 17th. Injection of 5 milligr.

December 18th. Injection of 7 milligr. Profuse perspiration; thirst; secretion trifling.

December 19th and 20th. Injection of 8 milligr. each. Temperature normal.

December 22d. Injection of 10 milligr. After twelve hours, temperature, 104° F.; pulse, 98; headache, restless. Six hours later, temperature, 97° F.

December 25th. Injection of 10 milligr. After twelve hours, temperature, 100.4° F.

December 27th. Injection of 15 milligr. Highest temperature, 100.4° F.

December 31st. Injection of 20 milligr. After sixteen hours, temperature, 101.2° F.; pulse, 120. Face pale, eyes sunken, marked anæmia, but appetite good. Iron.

No inoculations on January 3d and 5th, with afternoon temperature of 101.4° F., and pulse, 120.

January 6th. Injection of 30 milligr. Twelve hours afterward, temperature. 101.4° F., and pulse. 110. Eighteen hours afterward temperature. 101.1° F., and pulse, 112. Twenty-four hours afterward, temperature, 101.4° F.. and pulse, 112.

Inoculations were discontinued. General condition not changed. Fistula as deep as before. but secretion slightly less, purulent, contains bacilli. High degree of anæmia. Physical symptoms not altered.

Wilhelmine K——, aged nineteen, admitted December 11, 1890, for lupus vulgaris of upper lip, nose, and eyelid. Father died of pulmonary tuberculosis nineteen years ago. She had, when young, conjunctivitis, cervical adenitis, scarlatina, and measles; also eczema capitis. Lupus commenced eight years ago on the nose, and spread to upper lip and part of left cheek. Has been operated upon several times. The lower part of the nose is deformed by loss of substance, the nares impervious; the upper lip shows several hard cicatrices. Some noduli still present. Upper lobe of right lung somewhat dull. No bacilli found in sputum.

December 11th, 4.45 P.M. Injection of 1 milligr. Temperature rose to 100.2° F. within an hour; was subnormal, 97.2° F., within two hours; after five hours pain around site of injection; after seven hours, nose and lip congested and with the sensation of tension. Afterward some cough; little sleep. Redness and œdema of nose and cheek very marked within sixteen hours. Headache and dizziness. After eighteen hours, temperature 102° F., pulse 112° F., respiration 26. Nose and lip purplish; pain in chest; chilly, hot, perspiring. After twenty-four hours, temperature 101.2° F.

December 12th. Another inoculation of 2½ milligr. Pain; cough. Some distinct pustules in the area of lupus. Cough and rigor; temperature, 103.1° F.

December 13th. Itching of nose and lip. Temperature falls some; rises again to 103° F.; normal at 10 P.M. No injection. Still in the night two chills without a rise of temperature, and pain in left shoulder.

December 14th. 7.30 P.M. Injection of 4 milligr. Temperature rises after nine hours to 104.5° F. within fourteen hours; normal in twenty-six hours. Meanwhile four chills, headache, pain about chest. Nose and upper lip swelled and congested. Desquamation on nose.

December 16th. Injection of 5 milligr., with the same result as to temperature. Less local congestion, hardly a rigor, the newly-formed pustules and the noduli of lupus much smaller.

December 18th. Injection of 5 milligr.; highest temperature, 102.4° F. Coryza, scales fall off.

December 20th. Injection of 7 milligr.; highest temperature, 102.2° F.

December 22d. Injection of 8 milligr.; highest temperature, 101.7° F.

December 23d. Injection of 9 milligr. Highest temperature, 100.2° F.

December 24th. Injection of 10 milligr. Highest temperature, 99.2° F.

December 25th. Injection of 12 milligr. Highest temperature, 100.1° F. after the lapse of twenty-four hours.

December 26th. Injection of 15 milligr. Highest temperature, 99.9° F.

December 27th. Injection of 15 milligr. Highest temperature, 100° F. after twenty-four hours.

December 29th. Injection of 20 milligr. Highest temperature, 100.2° F. after twenty-four hours.

January 3d. Injection of 15 milligr. Highest temperature, 100° F.

January 5th. Injection of 15 milligr. Highest temperature, 99.4° F.

January 7th. Injection of 25 milligr. Highest temperature, 100.8° F. after twenty-two hours.

January 8th. Injection of 40 milligr. No rise of temperature. After thirty-three hours, 97.4° F. A few hours after the injection an attack of angina pectoris, pain, oppression, fear of impending death. Inhalations of amyl nitrite relieved her.

January 16th. Injection of 50 milligr. Highest temperature, 101.8° F.; pulse, 40.

January 18th. Injection of 60 milligr., without any reaction.

January 24th. Injection of 80 milligr. Some hours after, without a change of temperature, attack of angina pectoris, face pale, pulse so frequent as not to be countable. Pain and sense of constriction; distinct blowing murmur at apex. Morphine did not relieve her, amyl nitrite did.

January 29th. Injection of 30 milligr. No change of temperature, but palpitation and pain in chest. After seven weeks' treatment the lupus is very much improved, the deformed nose is of normal paleness, the lips still red in places, some lupus noduli on lip still perceptible, lip still hard, part of this hardness, however, due to old cicatrices resulting from operations. Though there be no cure, the improvement is such, when compared with the results of any operative procedures known, as to be very encouraging.

Amos D——, aged sixty-six, admitted December 31, 1890. Diagnosis: Epithelioma of face, right side (was announced as lupus). Ulceration of face was observed fifteen years ago. Many attempts at a cure. Lately in Chicago arsenic paste, with the result of digging a square large hole into the malar bone which is superficially necrotic, and destroying the external angle of right eye. Normal organs. Insisted upon lymph treatment.

January 1st. Injection of 2 milligr. Eruption began to rise half an hour later. Temperature was 101.2° F. after three hours; fell; rose again, until after twelve hours it reached 101.8° F. It was not normal until thirty-six hours after inoculation. Wound not changed, but eyelids swollen and red.

January 3d. Injection of 2 milligr. Temperature, 100.3° F. four hours after inoculation, and slight rigor.

January 4th. Injection of 3 milligr.

January 5th. Injection of 5 milligr. No increase of temperature; some pain in eye and about the site of inoculation.

January 6th and 7th. Injection of 10 milligr. each.

January 8th. Injection of 15 milligr.

January 9th. Injection of 20 milligr., after which, on the next day, temperature, 101.5° F.

January 11th and 13th. Injection of 25 milligr.

January 16th, 20th, 22d, and 30th. On the 19th he had once a temperature of 100.8° F., but in no connection with an injection.

January 25th. Injection of 40 milligr. Through all these days no rise in temperature, and no local effect. The wound healed slowly under a boric and salicylic acid ointment.

Reactions set in at first as they do in the well, in from one half to twenty-two hours. This effect was obtained with 2 milligr., while afterward 20 and 40 had no effect whatsoever. There was no apparent effect on, or improvement of, the local lesion attributable to the use of "tuberculin."

James C——, aged forty-one; admitted January 3d, for alleged lupus, which proved epithelioma of the eyelids and temporal regions of left side. It had lasted seven years and had undergone several operations in the last two years. Five milligrammes were injected January 4th at 4 P.M. at a temperature of 98.4° F. Nine hours later it was 97° F.; fifteen hours, 96° F.; seventeen hours, 98° F. During this time slight fulness in head, pulse smaller and somewhat quicker.

On January 5th injection of 10 milligr. Slight increase of temperature and swelling of spleen on the 6th.

On January 8th injection of 30 milligr. at 9 A.M. Temperature rose soon, and reached 103° F. within ten hours. Lymphatic glands enlarged on the side of his chest, which were quite painful.

January 11th. Injection of 40 milligr. Temperature rises only to 100.2° F. Feels perfectly well.

January 15th. Injection of 50 milligr., with no effect whatsoever.

January 18th. Injection of 33⅓ milligr. No effect.

January 21st. Injection of 66⅔ milligr. Temperature eight hours after, 101.4° F.; otherwise no effect either local or general.

January 25th. Injection of 87½ milligr. No effect at all; complains, however, on the 26th that his bones ache and his shoulders are lame. Better on the 27th.

January 28th. Injection of 72½ milligr. No effect, and the ulcerations in about the same condition as in the beginning; some new granulations on the edge of lower eyelid. No improvement.

(To be continued.)

Changes in the Myocardium in Valvular Disease.—Dr. Krehl subjected the heart in seven cases of chronic valvular disease to exhaustive microscopical investigation, and obtained some suggestive results. In every instance there were present disseminated endocarditis, pericarditis, endarteritis of the small arteries of the myocardium, and fibrosis with extensive muscular atrophy. These anatomical characters present the character of progressive inflammation, and are most extensive in cases perishing from failure of compensation. They are of a kind calculated to lower the cardiac activity, and their significance in practical medicine is readily appreciated. In every instance of heart disease that comes before us with symptoms of failure, particularly in cases of dropsy, we must inquire of ourselves what is likely to be the condition of the muscular walls which are liable to suffer in this way. Before we can employ digitalis, nux vomica, or other cardiac remedies with intelligence, we must do our best to estimate to what degree and to what extent the muscular tissue and its arteries, on which we intend these drugs to act, are free from inflammatory and degenerative changes. —*Centralblatt für klinische Medicin.*

REFLECTIONS AND OBSERVATIONS UPON THE FORMATION, STRUCTURE, FUNCTION, AND PATHOLOGY OF FISTULOUS TRACKS OR SINUSES;

Especially those which Constitute Anal and Rectal Fistulæ; and the Tendency of Such to Spontaneous Obliteration and Cure.

By WILLIAM BODENHAMER, M.D., LL.D.,

NEW YORK.

It will be conceded that the particular subject which the writer has selected for discussion on this occasion has been but little reflected upon of late by surgeons generally; either from not considering it of sufficient importance, or from not having had their attention especially and properly directed to it. It is a subject, however, in the estimation of the writer, which should not be altogether neglected, but is well worthy of further consideration.

Before entering fully upon the main features of the subject, the writer will endeavor to give the etymology, signification, and correct application of the word *fistula*, the importance of which will scarcely be called in question, especially when it is considered that there is perhaps no technical term in medicine more misapplied or indiscriminately used. A few brief remarks will also be made upon the importance and propriety of employing precise definitions and correct technical terms in medicine.

As language is the great medium through which we gain access to science and to art, we should therefore endeavor to make ourselves well acquainted and familiar with this medium. In the science and the art of medicine we too often have to deplore the great want of clear and precise definitions of diseases, as well as to lament the lack of attention to the nomenclature or vocabulary of technical terms. No technical terms in medicine, or in any science, should be used, except those which are truly appropriate in meaning, purely technical in character, and strictly uniform in application; all except such are liable to occasion false ideas, and consequently lead to erroneous practice; indeed, we all know there can be no accurate thinking, and of course no correct reasoning, without a precise and correct use of terms. The sentiments expressive of delinquency in this respect are not peculiar to the writer, as hundreds have long since expressed them and many more have felt them.

"Every science and every art," says an eminent author, "has its particular nomenclature or vocabulary of technical terms. These terms are generally derived from the Greek or Latin, because these languages, being now dead, and their words consequently not liable to change, are considered for this reason a better source than any other for words of this description. The convenience and utility of such terms are universally acknowledged; and they are preferred to other equivalent terms in common use in the language, because having no other meaning nor use that what belongs to them as technical terms, whenever they are used every person who understands the science knows precisely what is meant. The fact of their being of foreign origin, of fixed and determinate signification, and not employed in the language to denote anything else, is not only no objection to their use, but is in reality a decided advantage."

It is strange that some medical men, both in our own and in foreign countries, seem suddenly to have taken such an aversion to the dead languages, and to everything foreign, except their own particular mother tongue, and appear so much afraid that it is contaminated by such connection, that they are actually urging the abandonment of all Greek and Latin technical terms in medicine, and substituting in their stead either English, French, or German technical terms. But it is sincerely to be hoped, however, that the science of medicine in this respect will be spared for a long time to come from the manipulations of enthusiastic but, in the opinion of the writer, mistaken

innovators; for the radical change proposed would be well calculated to disturb, to distract, and to perplex, for a generation or two, professors, students, and practitioners. Indeed, it is by sudden and perpetual changes in medicine that the science and the art are constantly kept in a state of fluctuation and uncertainty, if not absolutely retarded. But the writer, by this language, does not wish it to be understood that innovation in medicine generally should be dreaded; far from it; for servile imitation is the grave of genius and the burial-ground of all improvement in medicine, which is both an experimental and a progressive art. The fear of innovation, therefore, should by no means arrest the march of real advancement, for it is the vehicle upon which medicine is carried from one degree of perfection to another; and although its speed may sometimes be retarded, as it often has been before, yet its extent can only be circumscribed by the acme of excellence in all human productions. The direction of medicine at the present day is onward and upward, and there is therefore still work for the medical men of the present and the future to do, and from present indications we conclude correctly that they will not fold their arms until they can say it is finished.

Description and Definition.—The Latin word *fistula* signifies a reed, hence a pipe or a hollow cylinder. The ancient Latins called a catheter *fistula*, and a clyster-pipe the same. Some authors, we think erroneously, however, derive the word *fistula*, from the Latin *fundo*, to pour out. The Latin term *fistula*, however, finds its true prototype in the Greek word σύριγξ, a pipe or flute, being derived from the verb συριξειν, to whistle. The Greeks, as shown, used the word *syrinx* to denote the same disease which the Latins call fistula. The ancient flute was a hollow cylinder, open at both ends; the modern flute is closed at the upper end. The name fistula, then, is very evidently taken from the similitude which the narrow cavity of a fistulous tube or track has to that of a reed, pipe, or flute. This word, however, has to a great extent become disqualified for technical use by its numerous untechnical applications.

The term fistula in pathology or surgery, then, simply denotes a narrow tube or conduit of variable length, leading to a free surface, from an abscess, cavity, or a normal canal, the seat of some local inflammation or irritation; and having a small orifice through which fluids or extraneous matters are discharged, greatly disproportionate to the extent of the morbid affection.

Paulus Ægineta says: "A fistula is a callus sinus, generally formed from an abscess, and derives its name from the pipes of reeds (fistulæ)." [1]

Celsus defines a fistula as follows: "Id nomen est ulceri alto angusto calloso." [2] Of all the ancients, Celsus has given the most minute, correct, and extensive description of fistulæ. Indeed, there is nothing extant on the subject any more appropriate, even at the present day. The word fistula was generally defined by the early writers thus: "Sinus angustus callosus profundus; acri sanie diffluens." In modern times, Dionis defines it: "Un ulcère profond et caverneux dont l'entrée est étroite et le fond plus large; avec issue d'un pus acre et virulent; et presque toujours accompagné de callosités." [3]

Mr. Pott describes a fistula as follows: "The smallness of the orifice of the accidental canal; the hardness of its edges; its being found to be the outlet from a deep cavity; its discharging a thin, gleety, discolored kind of matter, attended with great induration of the surrounding parts; are all of them circumstances raising and confirming the idea of a true fistula." [4]

It is observed that the Latin terms, fistula and sinus, are generally employed by many authors as synonymous, especially by the ancient writers; there is evidently, however, a difference, but in what it exactly consists is not so easily determined, in consequence of the numerous and various definitions and applications of it. A fistulous passage is narrow, or of small calibre, and may have an internal as well as an external orifice; whereas a sinus is much wider, and has but one orifice, which is external. Medical lexicographers, however, usually define it a gulf, a cavity, or depression; or a long, hollow passage, leading from an abscess, diseased bone, etc. But almost the same may be predicated of fistulous canals.

It may also be remarked here that the ancients, as well as some of the moderns, in their definitions of fistula, include callosity as an essential element; but this is an error, as there are many cases of fistulæ unaccompanied by callus, as the writer has often observed, as well as have others. In the early stage there is scarcely ever any induration and thickening of the tissues in and around the fistulous track; but in process of time these are brought about by frequent and long-continued irritating and inflammatory changes. This callosity in former times was considered to be of a scirrhous or cancerous nature, and subjected to very severe and injurious treatment. It is said by some authors that this callous condition of fistulæ was produced by the ancient treatment of the disease, which, they say, consisted of the introduction into the fistulous passages of highly irritating substances, on tents or pledgets of lint, which constantly so excited and irritated the fistulæ as tended strongly to produce this callous state of the parts. But neither such treatment by the ancients nor by the moderns is the cause of this callosity. Such treatment, however, is much more applicable to some of the moderns than to that of the ancients, who understood the nature and treatment of fistulæ as well as the moderns.

It is well known that more or less induration supervenes to inflammation, especially of the cellular tissue; and it is particularly observed in the callosities which follow the course of fistulæ in the anal region, which abounds in such tissue. The contraction and hardness in fistulous tracks take place very gradually, some considerable time after the acute inflammation, swelling, redness, heat, and pain in the cellular membrane are entirely dissipated. These callosities, however, do not usually produce any other bad effect than that perhaps of retarding the cure of such fistulæ.

The term fistula is often misapplied, or is used in an indefinite or vague sense, thus giving a very inadequate idea of the nature of the affection. Instead of simply denoting a pipe like or tubular sore, which is all that it does; or merely signifying the pipe, drain, or medium of conveying a fluid or extraneous matter to the surface, it is frequently applied to simple abscesses or to suppurating excavations, especially to all such in the vicinity of the anus. This departure, however, from its strict signification is doubtless caused in this instance by the fact that an abscess in the anal region most always precedes anal fistula, and that it is the initiative in the production of fistula. Abscess and fistula in the anal region stand in the relation of cause and effect; hence this complication is usually confounded and the term fistula made to include too much. This distinction, however, is important, and must not be lost sight of; for the indications in the treatment of simple abscesses and fistulous tracks are essentially different. An anal abscess may or may not result in fistula, but it is liable, from various causes, sooner or later, to become fistulous, and when it does the following is the process: After the pus in the first instance is evacuated, its parietes do not approximate, and its cavity is not spontaneously obliterated, and it establishes in its walls one or more pipes or canals which are fistulæ, and through which it discharges its secretions. An anal abscess may also become fistulous by its cavity gradually diminishing until it becomes itself a hollow cylinder or pipe. It is in this manner, then, that in time, a definite

organization is finally established constituting a fistula. An anal abscess may, however, under favorable circumstances, terminate without becoming fistulous. If the artificial or the spontaneous opening of the abscess is made sufficiently large to completely empty it at once, the extent of its cavity diminishes rapidly, and its parietes approximate, and we know, as in a wound, how they are simply agglutinated by means of the albumin and the fibrin, the blastema or blood plasma of the liquor sanguinis, which process either removes, or prevents the action of the peculiar accidental tissue which lines abscesses and fistulous passages, and which will be described hereafter. It is therefore highly important, if not contraindicated, than an anal abscess should be opened by a free incision just as soon as the slightest fluctuation can be detected in it.

An abscess, consequently, should not be called a fistula, until it has in time acquired the characteristics plainly specified in the term.

The word fistula is also applied to many other affections which have no claim whatever to the appellation; for instance, it is indiscriminately applied to the diseases of the lachrymal organs as well as to the following lesions: vesico-vaginal, urethro vaginal, recto-vaginal, recto-vesical fistulæ, etc. But where is the resemblance in them to the thing represented or signified by the term? These lesions or diseases are not fistulæ, but mere openings, breaches, or perforations; and their junction or communication is not effected by a pipe, tube, or canal. The great impropriety of denominating these affections fistulæ was demonstrated some years ago by MM. Jobert (de Lamballe) and Vidal (de Cassis).

Mr. Bryant, Surgeon to Guy's Hospital, London, has, however, very cleverly disposed at once of the incongruity of the application of the term fistula to the lesions or affections just mentioned, as well as to all others of a similar nature, by making an entirely new definition of fistula, strictly conformable to the exigencies of the case. He says, "A fistula is an unnatural communication between a normal cavity or canal, and the outside of the body, or second cavity or canal." [1]

It will be perceived, however, that the etymology and the signification of the word fistula are entirely ignored in Mr. Bryant's definition.

But it seems useless to expend any more words on the abuse of the term fistula, for there is no certainty that they will be heeded, inasmuch as the subject has been well and widely known to the profession for so many years; and especially, as some tell us, that the nomenclature of the disease is now so well understood and established that it is useless even to suggest any change in the application of the term. According to this notion, however, a word without any meaning whatever will answer just as well to denote a disease as a significant one, doubtless upon the principle that a rose is a rose and smells just as sweetly under any other name.

Formation, Structure, and Pathology.—The writer will now enter into a general consideration of the seat, development, organization, and properties of fistulæ.

It is known that fistulous canals may be developed in the different tissues of the body, but they are most frequently observed in the cellular membrane, and as this membrane is thickly dispersed about the margin of the anus and in the perineum, it is in these localities, therefore, that abscesses and fistulæ are most commonly developed. Indeed, the cellular tissue favors the formation and extension of these fistulous tracks, in consequence, doubtless, of the ready passage it affords to fluid matters, which often make their way rapidly in different directions in it with but little hinderance, it being the softest and most yielding of all the tissues of the body.

These fistulous passages, when they develop in the ano-perineal region, are generally single, but they often ramify at their extremities, usually communicating with each other, with one or more external openings, and converging generally to but one internal rectal aperture. Their direction is most frequently tortuous, yet they are sometimes straight, and they often present numerous contractions and dilatations in their course, and occasionally become insulated.

In the exploration of these often crooked passages, the probe, if straight and inflexible, cannot be made to follow the obliquities of them. The probe must be so flexible as to be capable of being bent or curved to such an extent, previous to its introduction, as to readily follow the track of the passage, and thus made, if possible to discover the exact extent, the true bottom, or the internal opening if any exists. These abnormal canals possess various degrees of sensibility; the introduction of the probe into them is sometimes productive of severe pain, while at other times the presence of the probe is readily tolerated.

The discharge from and through fistulous passages may present characteristics of pus, gleet, sero purulent, sanguineo-serous, or mucous matter; but the discharge varies like the cause; sometimes it is white and consistent, often it is thin and flaky, at other times pure, and again it is mixed with the product of some natural secretion, according to the location of the fistula, the general health of the patient, the length of time the affection has subsisted, etc.

M. Dupuytren treats the subject of fistulous passages in a very able manner. After giving their formation and structure, he says: "These accidental passages are formed at the expense of all tissues in their immediate vicinity, taking the elements of their organization from them—hence the fibrous, nervous, mucous, and osseous tissues may all enter into their composition, according to the locality of the fistula. Mucous tissue, osseous substance, nerves, veins, and cellular tissue, have been found in their organization, according to the parts in which they originated and through which they passed." [1]

The Adventitious Tissue.—The peculiar accidental tissue, previously alluded to, which lines the internal surface of these abnormal passages, bears some analogy, by its organization, properties, and functions, to the natural mucous membrane. Indeed, this peculiar tissue, which is neither a pseudo-membrane nor a mucous membrane, commences to be organized in all abscesses at a certain stage just before they spontaneously open, or are lanced; and it completely circumscribes the purulent collection in them; and should any of such abscesses subsequently result in fistulous passages, these will be found lined with the same kind of tissue.

Mr. John Hunter was the first to call attention to the existence of a peculiar tissue lining fistulous passages, apparently like mucous membrane. He says, "The internal surface of fistulæ has an appearance similar to that of a secretory membrane, and may be compared to the urethra." And again he says, "I believe that a deep wound, such as that from a gunshot, on proceeding to suppuration, and forming a fistulous canal, becomes in some degree analogous to an excretory canal, having the power of producing peristaltic motions from the bottom to the external opening." [2]

M. Dupuytren especially calls attention to the apparently mucous membrane which lines the inner surface of fistulous canals. He considered this peculiar tissue to be a real mucous membrane, similar to the normal mucous tissue, and differing from it only by the absence of follicles and a layer of epidermis.

M. Breschet has also produced an able article upon this subject, entitled, "General Reflections on Fistulæ and on the Formation of an Accidental Membrane in their Course." Of this membrane he remarks, "The organic elements of the adventitious membrane of fistulæ have the greatest analogy with those of the mucous membranes. This membrane is separated from the surround-

[2] A Treatise on the Blood, Inflammation, and Gun hot Wounds. 4to. London, 1794.

ing parts by a greater or less extent of cellular tissue which may be termed submucous, and it contains a portion of that structure in its composition, as may be demonstrated by maceration."[1]

No regularly developed anal fistula is destitute of this mucous-like tissue, lining its internal surface, and it is indeed essential to the formation of the disease; and in simple cases it is often the only organic change existing. According to MM. Dupuytren and Breschet, this tissue, in proportion as it acquires age undergoes considerable changes, becoming more and more like mucous membrane, and at a late period of its existence it will be found red, and its redness reveals many small blood-vessels which terminate on its surface by exhalants, the existence of which is evident by the secretion of fluids; and also, like the mucous membrane, it will be found soft and villous, and if examined with a glass the villosities may be distinguished.[2]

The few cases, however, in which the writer himself carefully examined this tissue, which were all, however, of recent origin, he found it much thinner, more delicate, and of a paler red color than the normal mucous membrane, neither was it as soft, velvety, and firm; and when examined with the glass he found its surface slightly tomentous and its texture filamentous, and the blood-vessels and villi were quite easily discernible. This tissue is evidently a low formation of the cellular membrane, and is of such a feeble character as to be easily removed by rubbing, scraping, or by the mildest escharotics, as the writer has often demonstrated.

Although this peculiar tissue possesses several strong traits of resemblance to the natural mucous membrane, yet the difference between them is so remarkable that their perfect identity can by no means be established or admitted. It may be said, however, that it is more analogous, perhaps, to the mucous membrane than to any other species of structure. M. Dupuytren considers this tissue to be a real mucous membrane, but admits that it is destitute of follicles and a layer of epidermis. This, however, is no inconsiderable difference, as it lacks the cuticle to protect it, and those important glandular bodies, the mucous follicles, which are dispersed throughout the mucous membranes, and secrete a viscous fluid for the lubrication of its surface. These, however, are not the only differences of organization between the accidental tissue and the natural mucous membrane. The former is known sometimes to be spontaneously effaced, and the fistulous passage it lines is obliterated; or it may be easily displaced artificially with the same result. This, under similar circumstances, however, cannot be said of the latter, inasmuch as such an occurrence is rarely or never observed. For instance, the mucous membrane of the intestinal canal, below an artificial anus, either in the groin or in the loin, remains normal and continues to secrete mucus, and the canal itself, too, remains pervious, although all the fecal matters are diverted from it, and no spontaneous obliteration ever occurs.

This peculiar tissue or enclosing cyst of abscesses, and which also lines fistulæ, has been called pseudo-membrane by some, but it is evidently not so, as can be easily demonstrated. A false membrane is known to be an exudation of a fibrinous character, chiefly from the capillaries of inflamed mucous membranes, and is deposited in layers on their surface, as in croup, diphtheria, etc., and is analogous to the exudation on serous membranes. Indeed this accidental tissue is neither a false membrane nor a false or a true mucous membrane, but it is *sui generis*. Lobstein has denominated it "tissu pyogenique."[3] He believed that the function of this tissue was really to generate or secrete pus, thus agreeing with Mr. Hunter, who, as has been shown, was the first to call attention to this tissue, and to suggest the idea that pus was its true secretion. But the writer has previously shown, however, that in abscesses this same kind of tissue which lines and completely encircles them, is organized subsequently to the generation or secretion of the pus; consequently it could not have had anything whatever to do with the process of pus generation. Indeed it would be much more plausible to suppose that this tissue was designed as a wall or barrier thrown around the abscess to confine it and its contents within bounds, and thus to prevent their spreading into the loose cellular tissue of the anal region, than to believe that its function was merely to develop or secrete pus. It, however, is not more of a pus-secreting tissue than are the mucous membranes themselves, which is certainly not their function. Yet, under inflammation, an ichorous fluid from their capillaries is frequently thrown out, which in reality, sooner or later, becomes muco-purulent or actual pus, without the least appearance of a solution of continuity; consequently can both the accidental and the mucous tissues be considered truly pyogenic?

It is also said by some authors that this accidental tissue is not only a pus-secreting but an absorbing agent also; yet it would seem that the instances must be few indeed in which pus would find its way into the circulation, from abscesses and fistulæ, through the medium alone of this tissue.

But after all that has been said and observed of this peculiar tissue, it must be admitted that there is much yet to be learned of a definite and positive character in relation to it; and it is only by means of new and further researches that the true nature, functions, and characteristics of it can be precisely determined.

Importance of Early Treatment.—It is not only important to prevent an anal abscess from becoming fistulous, but it is equally important, after fistulous passages have formed, to treat them radically at once, before their parietes and their internal lining tissue become perfectly organized by time, and thus become involved in serious pathological changes. Conservative surgery may especially be of essential service in the early treatment of simple and superficial cases of anal and rectal fistulæ, in asmuch as all such cases at an early period may be successfully treated without division or excision of the morbid parts.

"An opinion," says the late and able Dr. Gibson, "generally prevails that every fistula in ano requires an operation. There cannot be a greater mistake. So far from it almost every sinus, I am inclined to think, in a patient tolerably healthy might be healed if attended to in the commencement and judiciously managed. Nothing will contribute more to this end than absolute rest, simple dressings, moderate diet, and mild laxatives. I have known a fistula, protracted and kept open for months while the patient walked about, healed in a week by perfect quietude and the horizontal position."[1]

M. Breschet says: "By a judicious use of proper measures we may almost always spare the fistulous patient an operation, which, although generally exempt from serious danger, is nevertheless productive of more or less severe suffering, and often gives rise to very unpleasant consequences."[2]

The writer would here remark, however, that it must be distinctly understood that in all complicated cases of anal and rectal fistulæ, in which a large amount of the soft parts in the anal region, including sometimes the whole of one or both buttocks, are involved, attended with deeply burrowing sinuses and more or less external openings, no confidence whatever can be placed in any other treatment than in that which contemplates the complete division of all the passages, both external and internal, by either the ligature or the knife. When a deep fistulous track is divided by the knife, to aid in insuring success it might be well to scrape off or excise the accidental tissue and close the wound by suture. By the use

[2] Op. cit.

of the ligature, however, this proceeding is entirely obviated, as it completely destroys the accidental tissue and the callosity as it gradually divides the walls of the morbid track. These two methods, the ligature and the knife, have been thoroughly tested by ages, coming down to us as they do from ancient times. But it should be remembered that in the treatment of either the simple or the complicated form of fistulæ, much indeed depends upon the skill, the judgment, the experience, and the prudence of the surgeon to direct the application of the various and numerous remedial measures according to the exigencies of each individual case.

Indications in the Treatment of Simple Fistulæ.—The chief indication in the treatment of simple fistulæ, in patients otherwise healthy, is to destroy the accidental tissue which lines their internal surface, which, when accomplished, modifies the condition of their parietes, and, together with enlarging the orifices of the passages, and complete drainage, decidedly favors granulation, cicatrization, obliteration, and cure. The chief indication may be effected by means of various escharotics, some in the form of fluids, as injections, and others in the solid form. Some of the fluids which have been successfully used in some such cases, by the writer as well as by others, are the strong tincture of iodine; a strong solution of the nitrate of silver, say one drachm of the salt to one ounce of distilled water, and the following:

℞. Acidi carbolici..... gr. xxv.
Glycerine..... ʒ ij.
Aquæ destillat..... ʒ iv.
M.

A number of other escharotic solutions, suitable for injections in such cases, could here be given, for such abound, and are known, and will suggest themselves to practitioners generally, hence it is unnecessary to name them.

The writer has successfully treated quite a number of cases of simple and superficial anal and rectal fistulæ, in which there existed one or more straight or slightly curved fistulous tracks, by means of probes of silver or of copper, eight inches long, and of different sizes. The silver probe may be coated with the nitrate of silver, by dipping it several times in the fused salt, and introducing it the whole length of the track; or the copper probe may be coated with the nitrate of copper by dipping it in nitric acid, and inserted like the former. A choice can thus be made between the nitrate of silver and the nitrate of copper. The writer has had the most success with the latter. The former was the suggestion of Sir Benjamin C. Brodie, and the latter was that of Mr. Evans, of London. When a silver and a copper probe are dipped in nitric acid, and introduced together into a fistulous passage, the caustic effect is greatly increased, and if suffered to remain in too long would destroy the tissues with which they were in contact. This is the effect of the galvanic action set up by the contact of the copper and silver probes with the acid acting upon them.

Spontaneous or Natural Cure of Fistulæ.—The natural or spontaneous cures of anal and rectal fistulæ are not of frequent occurrence, yet occasionally isolated cases do present themselves in which a fistulous passage or passages will close and become obliterated without any surgical interference. Cases of this kind have long since been reported by such eminent men as Pott, Ribes, and Velpeau, and which emphatically demonstrate the fact that nature sometimes spontaneously effects cures of fistulous canals. This subject has, perhaps, not been sufficiently reflected upon by surgeons in general, for numerous circumstances point to the fact that nature itself attempts to cure fistulæ, and they who ignore nature's efforts in this respect lose some valuable points in their indications of cure of fistulæ by any method. In confirmation of this fact, the able Mr. Pott, in speaking of the tendency of fistulous passages to spontaneous cure, says: "They may not always become perfectly closed and heal; but the aim and conduct of nature is not therefore the less evident, nor the hint which art ought to borrow from her the less palpable."[1]

The following is, perhaps, the *modus operandi*, then, in which a spontaneous or natural cure of fistulous canals may take place: The composition of such canals is contractile, like all other tissues of the body; and just as soon as they, from some new action in them, begin gradually to cease giving exit to their accustomed discharge, or that which caused them, their cavities in the same ratio begin consequently to contract and become capillary, union and adhesion of their parietes take place, and finally they are changed into a fibro-cellular mass, resembling a cord, which may sooner or later altogether disappear.

A case of this very kind came under the observation of the writer at New Orleans, La., in March, 1847. Mr. P——, of Columbia, S. C., on a visit to New Orleans, brought with him his body-servant, George, a rather delicate mulatto about twenty-five years of age, who, soon after his arrival, contracted a severe cold, which rapidly terminated in pneumonia and death. Two years previously this man had a complete fistula in ano, which in less than a year closed and healed, without any medical or surgical treatment whatever. An autopsy was permitted the writer, who could distinctly feel the cord-like cicatrix, the remains of the fistulous track, and which he completely removed by dissection. It measured three and a half inches long, and its parietes were firmly united and had precisely the appearance and the feel of a cord. Since then the writer has observed four similar cases. Mr. Allingham reports twelve cases of spontaneous cures of anal and rectal fistulæ.[2]

"The fear of Pope Innocent was so great," says Saint Augustin ("Cité de Dieu"), "when they announced to him that it was necessary for him to be operated upon a second time for fistula in ano, that the surgeons on the day after found only a firm and solid cicatrix in the place of the sinuses and of the small openings which were seen the evening before."[3]

A knowledge, therefore, of the phenomena relative to the spontaneous cure of fistulæ is of considerable importance to the successful treatment of their various kinds, by whatever method employed, and should be an object of interest and consideration in the indications of their treatment and cure.

7 West Forty-Fifth Street.

PRACTICAL NOTES ON THE PROPHYLAXIS AND TREATMENT OF DIPHTHERIA.

By R. C. VAN WYCK, M.D.,

Poughkeepsie, N. Y.

The excellent article of Dr. J. H. Peck, in the Medical Record of January 31st, leads me also to add a few remarks and suggestions as to a plan that I have rigorously followed for the past two years, and which I have found to be eminently successful.

During the past two years I have had considerable experience in the treatment of diphtheria, and out of one hundred cases occurring in a daily routine of practice I have only to record one death. They were by no means mild cases, some of them being very malignant.

As regards prophylaxis, where isolation of patient can or cannot be practical, I direct all persons exposed to the contagion to use, either by spray, brush, or gargle, four times daily, a solution of peroxide of hydrogen, twenty-five per cent. This solution is odorless, much pleasanter, and as effectual, than a one per cent. solution of creolin. I have used, with excellent results, the vapor of cresoline once in twenty-four hours in the sleeping-

[1] Op. cit., p. 218.
[2] Fistula, Hæmorrhoids, etc., p. 16, 8vo. London, 1871.
[3] Mott's Velpeau, vol. i., p. 12. Imp. 8vo. New York, 1846.

room and through the house, by the aid of Page's vaporizer. I am directly opposed to such strong solutions of bichloride as 1 to 50 or 1 to 100. Such solutions, in my opinion, are unnecessarily irritating and caustic, and increase the inflammation. It is not always easy to apply them to the affected part, especially in rebellious children, and it seems to me such solutions should be applied only by the physician himself. For my part I have used the solution of bichloride 1 to 2,000, and painted it over the diseased surface with a camel's-hair brush used for the purpose. In one case of nasal diphtheria in a child four years of age, which seemed an almost hopeless case, the child had been sick three days when I saw it. It was a typical case of nasal diphtheria. Both nostrils were completely plugged with diphtheritic membrane; tongue dry and red; high fever, rapid breathing, and marked drowsiness. After acting on the secretions by moderate doses of calomel and soda, the entire nasal passage was syringed out every three hours with a solution of bichloride 1 to 2,000, alternating every three hours with a spray of peroxide of hydrogen, 1 to 4, in water. Brandy—one-half ounce—was given every hour in milk, and iron and quinine as tonics.

This treatment was continued for six days without causing any mercurial poisoning. The child recovered completely without any diphtheritic paralysis. My experience has been to use only those solutions which are unirritating. I have used the peroxide of hydrogen pure on the patch, either with a brush or small swab, being careful to get it only on the diseased part, as it is very irritating and will dissolve the patch very quickly, and is, in my experience, preferable to a strong solution of bichloride—1 to 50 or 1 to 100. I believe in every case of diphtheria it is necessary to use constitutional treatment at first; it excites the secretions, prepares the stomach for its duties to absorb medicines and nourishment, and often without any other treatment aborts the disease.

In treating a case of diphtheria it has been my custom to divide it into different stages: 1st, stage of infection; 2d, stage of invasion; 3d, stage of deposition of false membranes; 4th, stage of separation of false membranes; 5th, stage of complications, viz., albuminuria, paralysis, etc. By carefully recognizing the different stages the practitioner, by using appropriate remedies, will carry his patient through safely. The stage of infection is stated by Oertel as from two to five days. I have seen it develop in twelve hours. This is the stage when prophylaxis should be thoroughly adopted. The stage of invasion, characterized by general malaise, high fever, often vomiting, and rapid respiration, and coated tongue. In this stage I administer calomel, in my experience better combined with bicarbonate of soda; from 3 to 5, or even 10 grains of calomel rubbed up with about 2 grains of soda, and administered dry on the tongue every four hours, until the characteristic effect of it is seen by green spinach stools. When this treatment is used early the membrane will be limited, as shown by its thick and everted edges. At this time I use a spray of peroxide of hydrogen, 1 to 3 of water, and when the patch is limited to a circular area I paint with full strength of peroxide of hydrogen, being careful not to get it on the healthy surface, as it is a decided irritant. After all of the membrane has been gotten off by the spray, the mouth is gargled with pure water and the diseased surface painted with bichloride solution, 1 to 2,000. The painting done only by the physician three times a day, or by an intelligent member of the family. The spray of peroxide of hydrogen is used every two hours.

The atomizer that I have in use is one made by Ed. Schirmer, 209 Centre Street, New York. It is made entirely of hard rubber, having a long shank with two points, an anterior or straight, and a posterior curved, having three openings, so that it throws a fan-shaped spray. By the use of this point the posterior nares can be thoroughly douched. The advantage of this point, also, is that it is broad and will not injure the uvula or the palatine folds. Internally I have found this tonic very pleasant and effective:

℞. Potass. chloratis..... gr. lxxij.
Acidi hydrochlori dil.,
Tr. ferri chloridi..... ...āā ʒ ijss.
Aquæ..... ʒ ij.
Glycerini, q.s. ad mist.. ..... ʒ iv.

M. Sig.: One teaspoonful every four hours in one-quarter glass of ice-cold water, used as a gargle and swallowed, alternating with quin. bisulph., gr. iv., every four hours, two hours apart.

Milk punch is given every hour, and as strong as the patient can bear. In my mind everything depends upon the thoroughness of the application. By the use of this atomizer, it being long, the spray can be directed upon the part (the patient or some member of the family depressing the tongue), and not wasted on the back of the tongue and hard palate. I have never used creolin, but if anyone has used peroxide of hydrogen in sufficient strength and a good article, he will not wish anything better. It is a very unstable compound, and should be made fresh every day. I use it in the form of gargle, twenty-five per cent. solution.

Creolin has some objections. Its odor is offensive. H. Martin[1] gives a résumé of its use in over two thousand puerperal cases in the Breslau Lying-in Hospital. In three women who were having uterine douches of creolin solution, symptoms of intoxication suddenly appeared, such as anxiety, nausea, and fainting. A fourth woman was very restless and felt weak for several days. In these cases the urine drawn with a catheter was dark brown and contained albumin. The color disappeared in a few days, but the albumin persisted for a short time. The disadvantages are that the emulsions are not transparent, and the preparations are not always reliable.[2]

CANCER OF THE CERVIX UTERI WITH COEXISTING PREGNANCY—VAGINAL HYSTERECTOMY—RECOVERY.

By WALLACE TAYLOR, M.D.,

OSAKA, JAPAN.

In the September (1890) number of the *American Journal of Obstetrics*, there was a report of a case of vaginal hysterectomy during the early stages of pregnancy, for cancer of the cervix, by Dr. Mary A. Smith. The writer stated that she had been enabled to find but eleven recorded cases, and that the case then reported was the only one reported in America. Situated as I am in Japan, and not having access to records of important surgical operations, I had not supposed such operations were so infrequent; yet further consideration on the number of hysterectomies yet performed, suggests that the cases of vaginal hysterectomy during the early stages of pregnancy must necessarily be small.

As such cases are important and so infrequent, it is desirable that all such operations be placed on record where they can be readily accessible to the medical profession. Hence the following case, which came under my charge, though reported in the *Sei-I-Kwai*, a journal of limited local circulation, is presented for insertion in your journal.

Mrs. I. O'Y——, aged forty-one. Her menses began at fourteen and continued regular. She was married at twenty-four, has had six children and two abortions. The youngest child is six years of age, and the last abortion occurred two years ago. Her periods have been growing less and less for some time past, and she has missed the last two. She had a marked pallor, but otherwise appeared in general good health. She thought, however, that she might have some womb trouble, as she had some peculiar pelvic sensations. Upon examination the uterus was found enlarged, the fundus being felt above the pubis.

[1] Centralblatt für Gynäkologie.
[2] Journal of the American Medical Association, January 31, 1891.

The cervix felt as hard as a board, and the whole uterus, when grasped bimanually, felt as inflexible as a stick. With the speculum the cervix was seen to be nodular, elongated, and of a crimson color, but the projecting nodules of a bluish hue, and presenting the general appearance of a malignant growth. There was no areola around the nipple, no nausea, nor purple hue of the vagina. There was, however, a suspicious relaxed condition of the tissues within the pelvis that was thought might indicate pregnancy. The enlarged uterus might be due to disease of the body of that organ as well as of the cervix, especially since all felt so hard and unyielding, and the absence of the menses might be due to climacteric changes. The sound was not used, as we did not wish to complicate the case with abortion should pregnancy exist. The woman did not consider herself pregnant, nor were we inclined to consider her so.

The case was fully laid before the patient and her husband that she might be pregnant, but if she was, the progress of the disease would most probably be such as to render her death inevitable at, or soon after, her confinement; that her only chance for prolonged life was to submit to a radical operation at once, which we advised her to do. After due deliberation they asked for an operation, which was performed June 4, 1890, at the Choslum Hospital, Osaka, Japan.

Some incidents of the operation and subsequent course of the case only will be mentioned. In separating the bladder from the uterus the cervix was not hugged so closely as it should have been, and suspecting we might be encroaching on the bladder, a No. 20 French sound within the bladder was passed through into the incision, thus showing a rent had accidentally been made into that organ. Going back a few lines, a deeper layer of tissue was seized with catch-forceps, dissected up and drawn over the rent, clamped, and the dissection continued. On passing the finger through the opening posterior to the cervix, a knuckle of intestine was felt, and a prepared sponge secured with a ligature was passed up to the fundus of the uterus, to prevent any further descent of the intestines. The broad ligament was lifted up so high the finger could not be passed over it, hence the finger was bored through a thin portion of the ligament on the left side, as high up as could be reached, and with the closed scissors an opening was made in front through the peritoneum on the point of the finger as a guide, and the separation of the bladder from the uterus completed. That portion of the broad ligament beneath the finger was secured by forcipressure, and severed. The uterus, thus partially liberated from its attachments, could now be brought down so the finger was passed over the broad ligament, and the remaining portion was secured by a ligature and completely severed. The catch forceps securing the spouting points in the vaginal incision, and also the one applied over the rent in the bladder, were now removed. Though the uterus was severed from its attachments on the left, it could not yet be brought down so the finger could be passed over the broad ligament on the right side. It was accordingly dealt with in essentially the same way as on the left, except that the ovary and the tube with its fimbriated extremity were included in the ligature. The fundus of the uterus was now brought down by seizing it with catch-forceps one above the other and drawing down, and the uterus removed. The ovary and tube with its fimbriated extremity on the left were now brought down, ligated, and cut away. Thus the ovary and tube were removed with the uterus on the right side, but removed separately on the left. The sponge was now brought down and the parts further cleansed by sponging. During this manipulation blood began to well up between the forceps and the ligature on the left side, and in trying to expose the parts a strong flow of blood obscured the field and flooded the pelvis. The parts were at once brought down as far as possible and catch-forceps applied one after the other at the seat of hemorrhage; after four or five had been applied the hemorrhage was completely checked. One or two catch-forceps were also applied on the right side to secure oozing points. The parts were again cleansed by sponging, and a prepared sponge secured by a ligature placed in the incision. The patient's toilet was then completed, being left with two broad ligament-compressing forceps and eight catch-forceps projecting from the vagina.

The operation lasted about an hour and a quarter; if the delay on account of hemorrhage had not occurred, the operation would have been completed and the patient's toilet made within three-quarters of an hour. The patient stood the operation well. The pulse was somewhat weakened at the close, but the shock was not marked. Four hours after the operation, about the time the patient came out from the influence of the anæsthetic, the pulse became weak and irregular, and the patient restless with jactitations. I was sent for in haste, but being absent, did not arrive for fully an hour. I expected to find the patient exsanguinated, but instead she was quietly dozing, with no increased pallor or discomfort. The interne had promptly given her two drachms of brandy hypodermically and a hot enema of a saline solution, beef peptonoids, and brandy thrown high up in the rectum, and this had revived and quieted her. The gauze dressing being damp and stained, was removed, and the sponge to make sure all was safe. There was no hemorrhage, so a loose iodoform gauze packing was placed within the vagina. A few drops of bloody urine were drawn off. The patient was ordered the above enema and brandy every two hours, if symptoms of collapse again were manifested or if the pulse again became bad, and the urine to be drawn every two hours. The patient had a very quiet night after this, with no annoying symptoms. Some two ounces of bloody urine were drawn off ten hours ofter the operation, none being obtained before. The urine ceased to have a bloody tinge twenty hours after the operation, and the bladder held from four to six ounces without leaking. The forceps were removed from time to time, the last sixty hours after the operation. The ligatures came away on the seventh and eighth day. The bowels were moved by a saline laxative on the third day. The highest temperature was 38.4° C. on the fourth day after the operation, and the patient declared on the fifth day that she was as well as before she entered the hospital. She made a rapid and uneventful recovery; she was sitting up on the twelfth day, and walking about on the fifteenth, and left the hospital on the twentieth day after the operation, in good condition; the pallor having passed away and in its place was the tint of health. She is a pedler by occupation, and soon after leaving the hospital she resumed her vocation. I met her a few days since with a large pack on her back, and in response to my inquiries she said she was perfectly well and strong.

The extirpated uterus was five inches long, three and three-quarters inches broad from cornu to cornu, and two thick (antero-posterior). The fundus was soft and flexible, the cervix long and rigid, with a hard nodule the size of an almond on the anterior lip, two smaller nodules on the posterior lip and sides, and a fourth at the inner os including over one-half of the circumference of the cervix at that point; and on incision the cervix was found more or less indurated and affected throughout. Before operation it was thought that the condition of the cervix was such that, if pregnancy existed, the growth of the tumor in the next six months, till childbirth, would be such as to prevent the dilatation of the cervix and necessitate a Cæsarean section, with the death of the mother then or shortly after, though probably with a living child; and the condition of the cervix after removal was found to justify this opinion. Macroscopically, the tumor (especially before removal) was quite a typical specimen of scirrhoid carcinoma of the uterus, and microscopically, the small cell-groups and coarse, dense stroma were quite distinct. The uterus contained a fœtus one and three-quarters inch long from vertex to breech, of about two months.

One noticeable feature in this case was the rapidity with which the pallor passed away and was replaced by the tint of health. For, though the patient was recovering from a severe operation, yet by the twelfth day after the operation the pallor had all passed off, and the patient had recovered the ordinary glow of good health. This was also observed in a patient operated on, some two months previous, for carcinoma of the uterus. This patient had suffered from severe hemorrhage, and the pallor was extreme. Yet by the twentieth day after the extirpation of the uterus all indications of pallor and anæmia had passed away and there was in their place the tint of health. The rapid disappearance of pallor and constitutional disturbance under otherwise unfavorable circumstances, goes to show that the removal of such a diseased organ confers a benefit on the general system, over and above being rid of a diseased mass that may not be offensive, or that the patient may not even be conscious of, and is an additional reason for early operation in these cases.

ASTASIA AND ABASIA, WITH THE PRESENTATION OF A CASE.[1]

By GR.EME M. HAMMOND, M.D.,

NEW YORK.

Astasia and abasia is characterized by the inability of the affected individual to either stand or walk, but without the accompaniment of motor paralysis. A few cases of this interesting disease were reported by Charcot, Jaccoud, and Weir Mitchell, between the years 1883 and 1885, but none of these observers attached any especial significance to these particular symptoms. It was not until Dr. Paul Blocq's paper[2] appeared in 1888, in which he collected eleven cases of the disease under consideration, all, in fact, that had been reported up to that time, that the neurologist's attention was attracted to what the author considers a distinct type of a neurosis which differs in many respects from all other diseases characterized by disturbances of motion.

The patient, whom I have the pleasure of presenting to you to-night, consulted me over a year ago for nervous prostration brought on probably by too close application to her duties. She is not of a nervous temperament, her family history is good, and she has not been the subject of any serious illness, excepting Pott's disease which came on during childhood. Up to the time of her attack of nervous prostration she had never experienced the slightest difficulty in locomotion; had always been energetic; was always capable of taking charge of the affairs of a large household, and in fact, does so now. She is not nervous, timid, or hysterical. A significant fact, however, is that at the time of her illness she suffered from aphonia, which varied from time to time, sometimes being quite complete, at other times the voice was almost natural. Her difficulty in standing and in walking was of course not discovered till she was able to leave her bed. While in bed she was able to move her limbs freely into any position she desired. On regaining her strength sufficiently to walk around it was observed that she invariably walked by first advancing the left leg and then drawing the right one up to it, precisely in the manner which you have just witnessed. This she attributed at first to weakness, but in reply to questioning stated that if she attempted to stand on the right leg or to advance the right leg first in walking, she would fall over. On my insisting that she should make the attempt to walk naturally she did so. Immediately after the right foot touched the ground her body revolved rapidly to the right, using the right heel as a pivot. After making a revolution and a half she sank to the floor. I then assisted by standing facing her and allowing her to grasp my arms while I grasped hers. In this position I could prevent the body from revolving. On her attempting to walk I could feel by the traction on my arms that there was a strong tendency on her part to turn toward the right. This I forcibly overcame. The body was then alternately flexed on the thighs and then straightened again as in the act of salaaming. This was done several times and with great rapidity. If I then held the body so that it could not bend forward the thigh would become flexed on the trunk so that the foot would be raised about five or six inches from the ground. The leg would remain in this rigid position in spite of the greatest mental effort the patient could make to arrest it. There has never been any disturbances of motility in the left leg.

The physical examination showed the limbs were symmetrical, the muscles were firm and well developed. There was no paralysis. The patient while seated or while lying down could move both legs normally; with the right leg, however, it could be seen that a greater mental effort was required to make the movements than with the left leg. The patellar tendon reflex was normal on both sides. There was no ankle-clonus. There was no anæsthesia, hyperæsthesia, or any other disorder of sensibility in any part of the body, with the exception of slight loss of the muscular sense in the right leg. The electrical reactions, both qualitative and quantitative, were normal. Vision, the field of vision, and the color sense were examined by Dr. Dana in my presence, and were found to be normal. The senses of hearing, touch, pain, and temperature were likewise tested without anything abnormal being discovered. Lately I have encouraged the patient to make attempts at crawling on the hands and knees. The effort is attended with the same results that follow the attempt at walking, that is, she turns to the right and falls over. There is some resistance to passive flexion and extension of the right leg. These symptoms, then, of difficulty in standing and of incoördination and ataxia of movements for the act of walking but not for other muscular acts, correspond accurately to that condition described by Blocq under the title of astasia and abasia. Besides the eleven cases collected by Blocq three others have been reported, one by Berthet;[1] one by Mathieu;[2] and one by J. Siglas and P. Sollier.[3] These, together with the one presented to you to-night, make a total of fifteen cases. An analysis of these cases shows that although all of them were unable to stand or to walk on the affected limbs yet the character of the incoördinate movements varied in different cases. Thus there were violent trembling of the legs, complete paralysis only on attempting to stand, revolving to the right or to the left, ataxia, flexions of the leg on the trunk accompanied by rigidity, and flexion and extension of the trunk on the thighs (the salaam). All of the muscular movements were made rapidly.

In three cases there was slight hyperæsthesia alone, in two cases there was a moderate degree of anæsthesia. In three other cases there was hyperæsthesia on one side and anæsthesia on the other. The other seven cases showed no disturbances of sensibility. Except in two cases there was a diminution in the muscular sense. In two cases the visual field was restricted. The knee jerk was abolished in one case, exaggerated in one case, and normal in thirteen cases. Pain in the back was a prominent feature in three cases, and in one case there was amnesia. It will be seen at a glance at these cases that there are no constant symptoms present except the inability to stand and the inability to walk, and that these two conditions may depend upon severe clonic spasms, equally severe tonic spasms, and paralysis. It is a fact worthy of note that not a single case has been reported in which the upper extremities were affected. Blocq is of the opinion that astasia and abasia is a condition pathologically similar to agraphia, that is, that an individual affected with astasia and abasia has simply forgotten how to make the muscular move-

[1] Read before the New York Neurological Society, November 4, 1890.

[2] Archiv de Neurologie, vol. xv., January, 1888.

[1] Lyon Méd., 1889, lxi. and lxii.

[2] Gaz. des Hôpitaux, August 20, 1890.

[3] Archiv de Neurol., No. 59 (September, 1890).

ments necessary for walking. I do not see anything in these cases to substantiate this view. People afflicted with the disease under consideration can make the motions of walking perfectly well if they are allowed to lie down, but it has never been claimed that an individual suffering from agraphia can write any better in one position than he can in another.

It is only when the feet are in contact with the ground that the symptoms of astasia and abasia are manifested. The patient, while sitting down or lying down, possesses the power of moving the limbs freely in all directions, but the moment the muscles of the lower limbs are called upon to adjust themselves for the proper balancing of the body or to perform the automatic actions necessary for walking, they seem to lose all knowledge of their proper order of action and of their proper amount of contraction, and hence some muscles become flaccid while others are thrown into a condition of tonic or clonic spasm. It seems to me, therefore, to depend upon a loss of the power of adjusting muscular contraction, so as to retain an exact equipoise or equilibrium. This is, of course, a defect in the muscular sense. There is no known tract in the spinal cord disease of which will be followed by these symptoms. Blocq attempts to make a distinct neurosis of this class of cases, and claims that a differential diagnosis between hysteria and astasia and abasia can readily be made. In the latter disease there are no hysterical stigmata, he claims; no constant paralysis or constant contractures. But these latter are by no means characteristic of all cases of hysteria, and when it is considered that every case of astasia or abasia has been accompanied by some other symptom or symptoms, such as, for example, hyperæsthesia, anæsthesia, aphonia, contraction of the visual field, and temporary color blindness, all of which frequently accompany hysteria, and since the disease under consideration is purely functional in character, no gross macroscopical or microscopical lesion ever having been discovered in it, it will not be difficult to believe that astasia and abasia is merely an uncommon type of an hysterical affection.

Progress of Medical Science.

Varicose Ulcer of the Œsophagus.—A case of death due to hemorrhage from a varicose ulcer of the œsophagus is reported by Dr. Viti. The patient, a waiter of alcoholic antecedents, had been brought to the hospital in a state of extreme anæmia, the result of an abundant hæmatemesis which had taken place some days before, and died two days after admission, after bringing up about two litres of red blood. He had long suffered from pain in the epigastrium and vomiting after taking food. At the autopsy there was found marked anæmia of all the internal organs, with many old adhesions, especially between the capsules of the spleen and liver and the diaphragmatic peritoneum; the liver was smooth and normal in size and consistence, the spleen slightly enlarged and thickened, the kidneys healthy. The stomach, which contained more than a litre of blood, showed no dilatation of vessels or ulceration. On slitting up the œsophagus the mucous lining was seen to be pale, but bulging underneath, at the lower part of the tube were found enlarged veins with swellings at irregular intervals. About five inches above the cardiac orifice a tiny ulcer was found communicating directly with an enlarged vein underneath, the mucous membrane for some little distance round being considerably inflamed. The aperture was closed by a small blood clot, and it was from this spot that the hemorrhage had taken place. No other lesion was found to account for the bleeding. The œsophagus was the seat of sacciform dilatation just above the cardiac orifice, and the patient had been in the habit of making himself vomit in order to relieve the feeling of weight from which he suffered after meals.—*La Riforma Medica.*

Brown Pigmentation from Arsenic.—Dr. Förster records the case of a boy, suffering from Graves's disease, who developed bronzing of the skin after a long course of arsenic. The patient was ten years old, and besides the usual symptoms of that disease, had obstinate diarrhœa and rises of temperature which lasted some time. He was put on arsenic about the middle of July, and toward the end of September it was noticed that the face was somewhat yellow, and the skin of the trunk, formerly pale, had become brownish. In the following February, the face was again almost normal, as also were the forearms and hands. The whole neck, however, showed a brownish coloration extending to the upper part of the chest; and immediately under the nipples began a darker pigmentation which appeared deepbrown on the abdomen, while the back was somewhat lighter. The buttocks and the upper parts of the thighs were likewise dark brown, but got paler farther down. The two sides were equally affected. Arsenic had been administered without interruption for a period of nearly eight months. It was now diminished, and two months later the bronzing had become less marked generally and more circumscribed. The patient showed, eighteen months later, a faint brownish pigmentation on the chest and abdomen. Dr. Wyss recently published two cases of brown pigmentation after a long course of arsenic for chorea, under the name of melanosis. In one, a boy twelve years of age, the coloring was visible after six weeks' use of Fowler's solution, and in the following weeks it became quite marked. It disappeared, only to recur on the resumption of the drug. In a second boy, two years younger, pigmentation was observed after arsenic, in five to six weeks.—*Berliner klinische Wochenschrift.*

Plugging the Abdominal Cavity.—Dr. Walcher employs a new method of dealing with severe hemorrhage from the peritoneal cavity after the removal of tumors. Dr. Walcher combines drainage by tubes and gauze. He has contrived very wide glass tubes, with a channel one inch in diameter and from six to nine inches long. The tube is passed into the deepest part of the bleeding cavity or down to the bottom of Douglas's pouch. Then a strip of iodoform gauze about two inches broad is passed carefully down the tube till a good large bunch of the gauze presses against the bleeding part. In one case Dr. Walcher thus inserted a piece larger than a man's fist. The free end of the strip of gauze is left in the tube, which is closed with a plug of wool. An assistant presses the tube against the bleeding spot while the operator closes the abdominal wound. The tube is placed in the lower third of the wound. The gauze plug may usually be removed on the second day. By aid of a mirror, attached to the surgeon's forehead, the surface whence the bleeding proceeded may be examined. Should hemorrhage recur when the first gauze plug is withdrawn, a second plug must be passed down the tube. The objection to this plugging is its liability to cause retention of flatus. Two cases out of seven in Dr. Walcher's experience suffered in this manner for about two days. The abdominal wound in all the cases healed well, the portion at the site of the tube closing as firmly as the remainder.—*Centralblatt für Gynækologie.*

Secretion of Milk in the New-born.—Dr. Variot has observed a mammary secretion in quite a number of children of both sexes, varying in age from three days to nine months. In two cases the secretion was obtained in sufficient amount to permit of a quantitative examination, which showed that it contained the characteristic ingredients of milk, butter, casein, and lactose. Out of thirty-two infants only six were found to present no mammary secretion, though in many of the remaining cases it was very slight indeed, and in some did not present a milky appearance. The terms the author uses show a wide variation in the character of the secretion.—*Gazette Médicale de Paris.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, February 28, 1891.

FUNERALS AND CONTAGIOUS DISEASES.

STRENUOUS and very commendable efforts are being made by the Pennsylvania State Board of Health to prevent the spread of contagious and infectious diseases. Funeral directors and ministers of the Gospel have been enlisted in the work, and doubtless much good will result. Their assistance has been asked for and obtained through two addresses which, in pamphlet form, have been scattered broadcast throughout the State. One is by Rev. S. Bridenbaugh, of Norristown, Pa., on "The Dang r Arising from Public Funerals of Those who have Died from Contagious and Infectious Diseases," read before the State Sanitary Convention at Norristown, May 10, 1890. The other is addressed to undertakers, and is by Josiah S. Pearce, on "Precautions to be Adopted by Funeral Directors to Prevent the Spread of Contagious and Infectious Diseases," having been read in June, 1888, before the Funeral Directors' Association of Pennsylvania, of which he is the president. The views contained in both papers are sound, and could advantageously be spread all over the country. A grave responsibility rests on the man who prepares for interment the remains of one who died of infectious or contagious disease. The corpse and the furniture of the room of death are centres of infection, and it remains for the funeral director to decide whether the infection shall be stamped out then and there, or whether it shall start out afresh and invade other homes. With proper knowledge, energy, and firmness, he can obtain the former result. Such a desirable end, however, can only be uniformly reached by a State system of registration and examination of funeral directors, with stringent laws to govern them. In default of such regulations, however, the undertaker should use his influence to induce the family of the deceased to dispense with a public funeral in cases of scarlet fever, diphtheria, membranous croup, small-pox, varioloid, typhus fever, yellow fever, or measles. Newspaper notices should always state such causes of death. Friends and relatives should be prevented viewing the remains while awaiting sepulture. The undertaker should, in such cases, avoid using chairs, palls, or other articles which may be used at other funerals. An ice box should never be used. The main cavities of the body should be injected with a strong antiseptic solution, wrapped in a sheet saturated with some antiseptic, placed in a sealed coffin, and interred as soon as possible after death. The corpse, if a child, should not be carried in a carriage. All carriages used should be thoroughly disinfected, and, lastly, the undertaker should take pains not to be himself the means of spreading the contagion. He should have clothing set apart for use in just such cases, and should afterward bathe in an antiseptic solution. In addition to these recommendations the pamphlet gives details as to embalmment, disinfection, disinterment, and transportation of bodies. The address to the clerical profession is in much the same spirit, and requests that ministers absolutely refuse to hold public services where the deceased died of any of the diseases mentioned above. It also suggests that the clergy residing in cities or boroughs use their influence to have passed suitable health laws prohibiting public funerals in cases of contagious disease. Such recommendations are perfectly useless in many cities, as proper health laws are already in vogue; but the deplorable fact remains that in probably the great majority of municipalities there are no regulations, or, at least, very deficient ones. As an illustration are cited cases in which the ice used to preserve bodies dead from contagious disease was emptied out on the public street, and the box used on the same day in an uninfected house without having been disinfected.

THE LUNACY COMMISSION'S WORK.

THE Commission in Lunacy of the State of New York has finished the second year of its existence. The details of its work during that period appear in another column of this number of the RECORD. Since the organization of the Commission great changes have taken place in the asylum system of the State, chief of which, of course, was the passage of the "State care act," whereby the poorhouse system of caring for so called "chronic" cases of insanity was abolished and all cases committed given proper treatment in State hospitals. The Commission has carried out the law as far as possible, but a large number of cases remain under county care owing to a lack of accommodation in the State hospitals. About $485,000 are wanted to build additional buildings. The Commission has unified the systems of keeping accounts and statistics, has regulated the service of legal papers on the insane, and has stopped the abuse of certain hospitals accommodating wealthy private patients at the expense of the room of the poorer class. Following its recommendations also, the Commission of Statutory Revision is revising the statutes of the State relative to property rights of the insane, the determination of official responsibility in the escape of patients, and also the matter of the discharge of patients from custody being vested solely in medical officers. The Commission has made a number of new recommendations to the Legislature, a few of which are mentioned in the abstract printed elsewhere. They are all good and deserve the support of the medical profession, especially the one to establish a pathological laboratory for the study of insanity. The appointment of the Commission in Lunacy gave rise to considerable unpleasantness. It clashed with the State Board of Charities, with county poorhouse superintendents, and with the boards of directors of the several institutions under their supervision. Nevertheless it has not only de-

monstrated its usefulness but almost all friction has disappeared, improvement is manifest in every phase of the work. If "by their fruits ye shall know them" the Commission deserves hearty commendation. It should be granted greater power by the legislature. Centralization of government is carried out in all the great departments of the State and is equally applicable to the management of the asylum system.

THE STERILIZATION OF PREDIGESTED MILK.

The attempts to secure a perfect substitute for human milk, are, it is admitted, still not completely successful. The various preparations and special methods now in vogue in most cases do very well, but bottle-fed babies in institutions continue to die. Of late, sterilization of the milk has been widely adopted; and this process commends itself as at least freeing the fluid from dangerous impurities. But it has been asserted that sterilized milk is made thereby somewhat less digestible. Certain experiments made on this point by Dr. H. D. Chapin, hardly bear this out. Some later experiments, however, made by Dr. E. M. Hiesland, and published by Dr. B. C. Hirst (*Medical News*; January 31, 1891), have led to the following results: Dr. Hiesland found that by sterilization, 1. The albumin is coagulated. 2. Casein less readily precipitated by rennet than in normal milk. Acid corrects this condition. 3. Fat is freed to a slight extent; fat not freed has a lessened tendency to coalesce. 4. Sugar undergoes some change, as shown by its lessened dextro-rotary power. The considerations suggested by a knowledge of the foregoing facts are:

I. The coagulation of milk albumin by sterilization may render the milk more difficult of digestion. II. Sterilization interferes with the coagulability of milk by rennet, and presumably, therefore, with its digestibility by the gastric juice. III. Free fat, as found in sterilized milk, is probably not readily assimilated in infant food. The fat not free, being enclosed in a less easily destructible envelope, is probably slow of digestion.

In order to prevent the alleged injurious changes caused by sterilization Dr. Hirst suggests that the milk be partially predigested. His directions are:

1. Have ten nursing-bottles prepared clean every morning.

2. Take cream five ounces, milk two and one-half ounces.

3. Put in skillet; add pancreatin powder; heat over alcohol flame for six minutes; stir and sip constantly; *do not overheat.*

4. Of this mixture, put in each bottle six drachms (to make two-ounce bottle). Use funnel.

5. Add to each bottle ten drachms sugar solution.

6. Stopper the mouth of each bottle with dry, baked cotton, and sterilize for twenty minutes.

7. Set aside to cool.

8. Before use, put bottle in warming-cup; apply nipple immediately before giving it to infant.

Make sugar solution by dissolving one ounce sugar of milk (one powder) in a pint of warm water.

The pancreatin powder consists of two and one-half grains of pancreatin and five grains of bicarbonate of soda.

Partially predigested sterilized milk is thus put forth as the latest complete baby-food and perfect infant-raiser.

A TUBERCULOUS ENVIRONMENT.

If one can trust the statements of veterinarians and official cattle inspectors, the great cities of the East are surrounded by an army of tuberculous milch-cows, which constantly menace the health of the people. The facts asserted are that, in Massachusetts, particularly in the eastern part, ten to twenty-five per cent. at least of cattle are tuberculous.

Dr. Bailey, State Veterinarian of Maine, gives the following estimates of experts:

"Dr. Alford H. Rose, United States Inspector of Cattle at Littleton, Mass., says that Suffolk and Middlesex Counties are literally overrun with the disease, and Dr. William A. Rose, United States Inspector at Washington, D. C., told me, after examining more than two hundred herds in Massachusetts, that he had not been into a single herd in which he could not identify more than twenty-five per cent. of tuberculous cattle. Dr. Madison Bunker, of Newton, Mass., Drs. Hitchings, Penniman, Colburn, and Winchester, all give their estimate as from twenty-five to fifty per cent., and Dr. Winchester writes that he does not believe there is a sound herd of cattle within twenty miles of the city of Lawrence, where he lives."

There is no particular reason for supposing that the condition of affairs is any better in the neighborhood of this city or Philadelphia. We must express some doubts, however, as to the correctness of the statements made above by the veterinarians. There is a polemical and a business element which may produce some bias. Apart from this, we doubt the ability of the veterinarian to recognize tuberculosis in cattle with the certainty which he seems to feel. The human physician does not pretend to diagnosticate phthisis for purposes of careful record without first making a bacteriological examination of the sputum. And we should naturally refuse to accept the statement of a veterinarian who, without such tests, announced that there "was not a healthy herd of cattle within twenty-five miles of the city."

There is evidence enough of the danger of bovine tuberculosis to make it imperative that sanitary authorities institute a careful examination of herds furnishing milk to cities. But the matter is not helped by sensational announcements to the effect that half of our milk-supply is diseased.

People are getting afraid of drinking water, and if there is a panic over the milk, there will be nothing left to drink but broths and alcohol.

Prevalence of the Grip in Japan.—The influenza is still as prevalent as ever in Japan. It would be difficult to find a foreign household which has escaped, while in Japanese circles it is said to be as bad. The Emperor and Empress are reported to be among the sufferers. Reported cases of influenza among the Japanese in Yokohama alone amount to fifty thousand. The number of cases not reported is said to be very large.

News of the Week.

Dr. Richard Quain has been made a baronet.

The Name "Tuberculin" is not a new one. A homœopathic remedy which is a dilution of phthisical sputum has been known as tuberculinum.

A New Neurological Journal.—A new German journal, specially devoted to neurology, is about to be published, under the editorship of Professors Erb, Lichtheim, Schultze, and Strümpell. The new periodical will be entitled *Zeitschrift für Nervenheilkunde*.

Dr. Marius Duvall, Medical Director of the United States Navy, retired, died suddenly last week at his home in Baltimore. Dr. Duvall was nearly seventy-three years of age.

Honor to the Memory of the Late Dr. Mathews Duncan.—The annual meeting of the Obstetrical Society of London, on February 4th, was remarkable in several respects. Eighty-five persons were present, including eleven visitors. When the President, Dr. Galabin, began an obituary notice of the late Dr. Mathews Duncan, in the course of his annual address, the Society rose, and remained standing till the speaker had concluded his observations on the life, work, and character of the great obstetrician.

A New Scientific Society.—A new society, entitled "The American Anthropometric Society," has lately been founded at Philadelphia, under the presidency of Dr. J. Leidy, Professor of Anatomy in the University of Pennsylvania. Professor Virchow has been elected Honorary Vice-President. Its object is to have studies made of the brains of the members after they are dead. It is of the same character as the Mutual Autopsy Society which was started in this city some years ago, but which died before any of its members.

Sudden Death.—Dr. George D. Wilcox, of Providence, R. I., presented the Medico-Legal Society of that State a paper upon "Sudden and Unexpected Death," which is published in the *Medico-Legal Journal* of December, 1890. He tells us that over three thousand sudden deaths occur annually in England and Wales from unascertained causes. Among the causes that have been found he enumerates the following: Ambulatory typhus, pneumonia, peritonitis, and meningitis. Such affections may run a latent course, and be unsuspected until they end in sudden death. A circus clown fell dead in the midst of his performance; the autopsy revealed an immense single tubercle of the brain. Cerebral congestion, hyperæmia, anæmia, hemorrhage, serous exudation, compression, and concussion, all have contributed to sudden death.

Dr. Stevens G. Cowdrey, Surgeon in the United States Army, died on February 22d, in this city. Dr. Cowdrey came east from Santa Fé, New Mexico, in December, on a leave of absence. Dr. Cowdrey was born in New Hampshire in 1838. In 1848 he was appointed Assistant-Surgeon in the regular army, and last year was given the rank of Major.

The Harvard Medical Society of New York City, composed of graduates of the Harvard Medical School residing in New York, has recently been organized, with Dr. Rufus P. Lincoln as President, Dr. Paul F. Munde as Vice-President, Dr. Dillon Brown as Secretary, and an Executive Committee consisting of the President, the Secretary, and Dr. Frederic R. Sturgis, Dr. William J. Morton, and Dr. Henry C. Coe. Meetings are to be held on the first Saturday of each month, except June, July, August, and September.

A Society called the American Morphological Society has been organized in Boston.

The Columbian Fair and Medical Work.—The Standing Committee on Medical and Surgical Congresses of the Chicago World's Fair is as follows: Dr. N. S. Davis, Dr. H. A. Johnson, Dr. H. M. Lyman, Dr. J. S. Mitchell, Dr. R. Ludlam, Dr. R. N. Foster, Professor Oscar Oldberg, and Benjamin Butterworth, Secretary.

Dr. Henry W. Stevens of this city, assistant pathologist to the New York Hospital, died on February 22d, after what seems a very mysterious illness. On January 23d he performed an autopsy on the body of a man who had died of hydrophobia. He had previously injured his forefinger while dissecting. The sore on the finger was not healed at the time, and, to guard against danger, Dr. Stevens underwent a series of injections at the hands of Dr. Paul Gibier, of the Pasteur Institute, beginning January 26th and ending February 9th, when he was seized with paralysis of the lower limbs and severe nerve pains. His disease steadily progressed, assuming the features of multiple neuritis. The case suggests that of paralytic rabies, such as has been reported by Horsley and Bristowe. The shortness of incubation seems to make it unlikely, if not impossible, that it should be due to inoculations. Dr. Stevens was thirty-three years of age, and was universally considered to be a rising man.

The Middletown Insane Asylum receives nearly $100,000 annually from private paying patients, and it is thought that too many of the rich are taken there. A bill has been introduced at Albany to exempt the asylum from the operation of the law requiring State care of the pauper insane. This law obliges the Middletown Asylum, as it does all others, to receive pauper patients first, and not take pay patients, except under special conditions, until the paupers are provided for.

Legal Regulation of the Doctors.—The Georgia Legislature recently tried to enact a law to prevent its doctors from getting drunk, and now Missouri is to consider the advisability of limiting the fee for a visit between 8 A.M. and 9 P.M. to one dollar, and for an office prescription to fifty cents.

Office Thief Around Again.—He is tall, about six feet, slim, black mustache, weighing about one hundred and thirty pounds, respectable in appearance, and well dressed, speaking English first, then German. He visits at a time when he knows the physician not to be at home. He visited a physician in this city on Saturday at 4 P.M., and relieved him of "instruments, cigars, opera-glass, a ladies' pin, not forgetting to take the key of the office-door with him."

The Duty on Tuberculin.—It is decided that twenty-five per cent. duty *ad valorem* shall be collected on tuberculin.

St. Luke's Hospital has purchased the House of Rest for Consumptives, and will maintain forty-five beds there for consumptive patients.

Treatment of Lupus.—At the last meeting of the Society of the Alumni of Charity Hospital, February 10, 1891, Dr. Clarence C. Rice read a paper on "Lupus of the Nose and Throat," with a demonstration of cases under the Koch method of treatment. The paper elicited a lively discussion, and the cases shown by Dr. Rice prove without a doubt the great value of Koch's lymph in lupus.

Koch and Cabinet.—The following very suggestive advertisement appears in an exchange, alongside an announcement of a Koch institute: "For sale, a pneumatic cabinet for treatment of consumption."

The Prevention of Narcotic Inebriety.—At a meeting of the American Association for the Cure of Inebriety, held February 18th, at the Academy of Medicine, New York, Dr. J. B. Mattison, of Brooklyn, offered the following preamble and resolutions:

"*Whereas*, a leading cause of morphinism, chloralism, and cocainism is the facility with which morphine, chloral, and cocaine can be procured from pharmacists; and,

"*Whereas*, the refilling of prescriptions containing these drugs is a potent factor in the rise and growth of these diseases; therefore, be it

"*Resolved*, As the sense of this Association, that no retail druggist should sell morphine, chloral, or cocaine, except on a physician's prescription. That no prescription containing morphine, chloral, or cocaine, should be refilled except on the written order of a physician."

These were unanimously adopted, and a committee consisting of Drs. Mattison, Crothers, and Wright, was appointed to secure legislation along the line of the resolutions.

The Medical Society of the Missouri Valley.—The next meeting of the Medical Society of the Missouri Valley will convene at Omaha, Neb., March 19th, at 7.30 P.M.

Wisconsin Medical Practice Law.—The Wisconsin Legislature has recently passed an act creating three Boards of Medical Examiners, representing the Wisconsin State Medical Society, the Homœopathic Medical Society, and the Eclectic Medical Society of the State, respectively, each board to consist of three members appointed by the Governor.

Why not Ligate the Vas Deferens?—Dr. F. Deppler has the following to say regarding the effects of castration on woman, and its usefulness in promoting Malthusian ideals: The sexual desire remained, and was the more pronounced the earlier in life the operation was performed. The operation offers no impediment to marriage; three of the author's cases had married and had lived happily with their husbands for years. A marriage with a castrated woman is the ideal Malthusian marriage, and the only way the Malthusian idea can be carried out without endangering the health and happiness of the woman.

The People's Bath.—A new and attractive bath-house, on the most modern and approved plan, is about to be erected under the auspices of the New York Association for Improving the Condition of the Poor, adapted for use during the entire year and arranged for the use of both sexes.

The Building Committee is composed of Mr. William Gaston Hamilton, Dr. Gouverneur M. Smith, and Messrs. Roland Redmond, John E. Alexandre, and George Blagden. The architects are Messrs. J. C. Cady & Co. The structure will be built among the residences of the poor, in the rear of the Broome Street Tabernacle, and facing Centre Market. While the bath-house will be free to the most destitute, it is probable that admission fees of either two, three, or five cents will be charged to others, which will include soap and towels, and possibly in winter a cup of hot coffee. The question has arisen, will the poor of this city avail themselves of the privileges of cleanliness about to be afforded them? General Booth in his work "In Darkest England," etc., in describing a slum says, "None of the sufferers will entertain the thought of seeking a hospital. One probably voices the opinion of the majority when he declares that 'they'll wash you to death there.' For these people a bath possesses more terror than the gallows or the grave." We must hope that the American idea will be that "Cleanliness is next to Godliness."

Paralysis from Hypodermic Injection of Ether.—A Vermont physician writes to the *Times and Register* as follows: "I injected thirty minims of Squibb's ether into the forearm of a patient in collapse, and whiskey afterward, and am accused by a physician in another town of causing a loss of motion, which now exists, in the hand and forearm. The patient belonged to another physician, and I was called in his absence. The next day it was discovered that the power to use the arm was gone, and now, although improved somewhat, the hand is useless. I am on good terms with the patient, and there is no suit going to arise; but I am being injured in my practice by the report which has spread. Now, if an injection of ether can injure a nerve or cause such trouble, the profession should know it; and I want to know it also, so as to be on my guard." It has been shown by Arnizan and Salvat, and also by Petres and Vaillard, that hypodermic injections of ether may produce a local destruction of the nerve-fibre just as if a section of it with a knife had been made. Of course, paralysis and anæsthesia may follow. A good many cases of such accidents from the injection of ether have been reported. The patients recover, but still there is harm done; and physicians who inject ether hypodermically should never insert it in the arm or legs, but always in the trunk; and the injections should be superficial.

Salol in Enteric Fever.—Dr. Hirtz employs salol to produce intestinal antisepsis. In enteric fever he gives a dose of 3 j. in the twenty-four hours, with salicylate of bismuth. He thinks that by this medication intestinal antisepsis is better attained than by naphthol, and it has the advantages over the latter that it is well borne by the patient and also disinfects the urinary tract. In the intestine salol is decomposed into phenic and salicylic acids, which are powerful antiseptics and antipyretics. He gave salol in daily dose of 3 jss. for three weeks to one patient, without causing any gastric disturbance.

FURTHER CONTRIBUTIONS TO THE PATHOLOGY OF THE LYMPH.

The most conflicting clinical reports on the results of lymph treatment still continue to appear in our foreign exchanges. In France Koch's fluid has been violently denounced. Scarcely a single note of praise is heard in the general chorus of utter condemnation. In England there is a manifest tendency to reserve judgment until more is known, although an undertone of enlightened scepticism can be noticed. Even in Germany professional opinion is still very much divided as to the real merits of tuberculin, while in Austria some severe strictures on Koch and his method have been published.

It is impossible to properly sift the numerous clinical records that have found their way into print; but several contributions to pathological histology have just been made that are deserving of notice. Professor Rindfleisch has studied the effects of Koch's lymph upon tubercular deposits, and he concludes that tuberculin has unmistakable healing properties (*Deutsche Medicinische Wochenschrift*). This is particularly noticeable in intestinal ulcers. He is unable, however, to verify Koch's assumption of tissue necrosis. According to Rindfleisch the lymph excites acute inflammatory changes around the tubercular nodules. There results a sharp line of demarcation between tissue which is hopelessly doomed, and that which is still capable of cicatrization. A tubercular deposit is a granuloma. Under lymph treatment the round cells of this granuloma tend to assume a spindle shape, the spindles become joined so as to produce fibres, and an ordinary fibrous cicatrix is finally formed. Thus, according to Rindfleisch, instead of necrosis and sloughing, cicatrization of tubercular deposits is invited by the lymph.

Theorizing on the possible effects of the fluid, Rindfleisch is willing to admit that, in a concentrated form, it may lead to necrosis. But in the ordinary dilutions employed in treating human patients, he suggests that immunity against tubercular infection may be hoped for, on the principle underlying ordinary vaccination.

Dr. Schimmelbusch, of Bergmann's clinic, has arrived at somewhat similar conclusions, although he has pursued an entirely different method of investigation. Instead of utilizing the pathological material of the dead-house, he has excised portions of skin and mucous membrane from living patients, in various stages of the Koch treatment. About thirty patients supplied him with abundant material for microscopical studies. Cocaine anæsthesia was used in performing the excisions.

He, too, was unable to find any evidence of tissue necrosis in the tubercular nodules. He points out that lupus should readily show this coagulation necrosis, or cellular disintegration, if such processes were really induced by the lymph. What he did find was merely an exudative inflammation around the tubercular deposits. Of course, he does not dispute that ulcerative destruction of tubercular nodules may be indirectly hastened by the lymph, if such destruction is already under way. The well-known tendency of tubercular infiltrations to break down may possibly be promoted by Koch's lymph, but it does not itself produce necrosis. It is an excitant of inflammatory action.

Lormenburg claims that pulmonary cavities do well under combined surgical measures and inoculation treatment. He speaks of the "cleansing" of cavities.

Professor Ehrlich and Dr. Guttmann have examined the blood of Koch patients, without result as to the finding of tubercle bacilli.

Virchow, in order to show his impartiality, demonstrated a further series of specimens at the last meeting of the Berlin Medical Society. Intestines were shown, in which some tubercular ulcers were evidently healing, although other ulcers did not show a process of repair. But an interesting specimen was also exhibited, in which reparative action was evidently taking place at the time of death, although no lymph had been injected.

The latter observation is undoubtedly a timely one, as the lymph enthusiasts are apt to forget that tuberculosis has been found amenable to treatment before the advent of tuberculin.

It is unnecessary to make any further comment on this, the latest phase of Koch's discovery, than to repeat that the interesting subject is not yet ripe for final judgment.

Reviews and Notices of Books.

The Patients' Record, for the Use of Physicians and Nurses. Compiled by Agnes S. Brennan. New York: The Knickerbocker Press, G. P. Putnam's Sons.

It is universally conceded that, in the proper treatment of any case, it is of immense value, a necessity almost, to keep a detailed record of the condition of the patient. There are many books compiled for this purpose, but none excel, if any equal, the admirable work just compiled by Miss Brennan. With a long experience as Superintendent of the Bellevue Hospital Training School for Nurses, and recognized as a leading teacher in her chosen profession, she knows just what is needed and how it can be placed in the most convenient form. Her work answers every requirement. There is space for the record of temperature, pulse, respiration, medicine, nourishment, stimulants, and urine, as often as it may be wished to make that record. There are slips inserted for the physician's orders, and there are also a dozen independent detachable temperature charts of the most improved pattern. Inferior books, note-books, and slips of paper, need no more be used with this book in the market, and with such a record properly kept there will be no excuse for mistakes.

Text-book of Materia Medica for Nurses. Compiled by Lavinia L. Dock, Graduate of Bellevue Training School for Nurses, Superintendent of Grace Memorial House. Pp. 201. New York: The Knickerbocker Press, G. P. Putnam's Sons.

Trained nurses should be well posted in materia medica. They should know the preparations, appearance, doses, poisonous symptoms, etc., of the drugs which they deal out to their patrons. Of therapeutics, it is not necessary that they should have an extended knowledge. That is in the realm of the physician. It is on these lines that the trained nurse is taught in our training schools. Heretofore there have been no text-books adapted to them. Either they were too exhaustive, going too deeply into physiological actions and therapeutics, and likewise expensive, or they were too concise, presupposing an amount of knowledge that the ordinary nurse doesn't have. Miss Dock, in her book, proposes to fill this middle place, and she does it admirably. After her graduation at the Bellevue Training School she was an assistant superintendent and a teacher whom the nurses justly admired. Consequently she knows what is wanted and needed by them, and this she supplies. The work is interesting, valuable, and worthy a position in any library.

The Time Relations of Mental Phenomena. By Joseph Jastrow, Professor of Psychology at the University of Wisconsin. Pp. 60. New York: N. D. C. Hodges.

This is one of that very excellent series of "fact and theory papers," issued by *Science*. The careful study of the subject is useful, the author says, in that it serves as an index of mental complexity, it indicates a mode of analysis of simpler mental acts, it demonstrates the close interrelation of psychological with physiological facts, and it suggests means of lightening and shortening mental operations. The gifted writer then proceeds to study and expatiate upon his subject in a manner that is at once very deep, interesting, and instructive.

Diseases of the Eye. By Edward Nettleship, F.R.C.S., Ophthalmic Surgeon to St. Thomas' and Royal London Hospitals. Fourth American from the fifth English edition, with a chapter on Examination for Color Perception, by William Thomson, M.D., Professor of Ophthalmology in the Jefferson Medical College of Philadelphia. Pp. 492. Illustrated. Philadelphia: Lea Brothers & Co.

The new edition of this work will be very welcome. It is an improvement on the old, having many useful additions to the text, and a number of handsome new plates.

A Manual of Auscultation and Percussion. Embracing the Physical Diagnosis of Diseases of the Lungs and Heart, and of Thoracic Aneurism. By Austin Flint, M.D., LL.D., Professor of the Principles and Practice of Medicine, and of Clinical Medicine in the Bellevue Hospital Medical College. Fifth Edition, thoroughly revised, by J. C. Wilson, M.D., Lecturer on Physical Diagnosis in the Jefferson Medical College. Pp. 268. Illustrated. Philadelphia: Lea Brothers & Co.

Ten years ago Professor Flint issued his work on physical diagnosis. With unsurpassed advantages for clinical study, of an original, investigating mind, and gifted with an unusually strong, facile pen, Dr. Flint was just the man to produce a good work. He did. It immediately took a first rank and has since retained it. No similar work has been more studied nor more relied upon. The book contains the results of Dr. Flint's original investigations, but its chief value, as the editor says, lies in the clearness and appropriateness of its style, the accuracy of its statements, its scientific method, and the practical treatment of subjects at once difficult and essential to the student of medicine. The work is a classic, and the present edition, with the additions that progress makes necessary, will be warmly received.

A Practical Treatise on Impotence, Sterility, and Allied Disorders of the Male Sexual Organs. By Samuel W. Gross, A.M., M.D., LL.D., Professor of Principles of Surgery and Clinical Surgery in the Jefferson Medical College, etc. Fourth Edition, revised by F. R. Sturgis, M.D. Pp. 175. Philadelphia: Lea Brothers & Co.

Three editions of Professor Gross' valuable book have been exhausted, and still the demand is unsupplied. Consequently Dr. Sturgis has revised and added to the previous editions, and the new one appears more complete and more valuable than before. Four important and generally misunderstood subjects are treated—impotence, sterility, spermatorrhœa, and prostatorrhœa. Impotence and spermatorrhœa are shown commonly to depend upon reflex disturbances of the genito-spinal centre, induced or maintained by lesions of the prostatic urethra. In the chapter on sterility the abnormal conditions of the semen that make it unfruitful, and the causes for such abnormality are fully considered. Sterility is shown to be the fault of the husband in at least one-sixth of the cases, and hence this subject deserves especially careful study. The book is a practical one and, in addition to the scientific and very interesting discussions on etiology, symptoms, etc., there are lines of treatment laid down that any practitioner can follow, and which have met with success in the hands of the author and editor.

Atlas von Beleuchtungsbildern des Trommelfells. By Von Dr. Kurd Bürkner. Jena. 1890.

This work consists of fourteen tables of colored chromolithographs giving views of the drum-head in various acute and chronic inflammatory processes of the middle ear. The author is director of the Aural Department of the University Poliklinik, Göttingen, and this painstaking work is intended to fill a want long felt in clinical instruction, no complete work of the kind having been offered the profession since the admirable works of Hinton and Politzer, which came out over twenty years ago. Table I. represents the normal drum-head and ruptures by both direct and indirect force. Table II. shows effect of ecchymosis, pigmentation, acute inflammation of the drum-head, fracture of the malleus handle, etc. Table III. exhibits acute and chronic inflammation of the drum head. Table IV. Cholesteatoma, exostosis, and various anomalies in connection with otitis media acuta simplex. Table V. Appearance of drum-head in effusion of fluid in the drum. Tables VI., VII., and VIII., represent various anomalies due to suppurative and non-suppurative chronic processes in the middle ear. Table IX. illustrates the appearances in acute purulent otitis media. Tables X., XI., XII., XIII., and XIV., show the many results of chronic purulent inflammation of the middle ear.

Transactions of the American Gynecological Society, for the Year 1890. Edited by Henry Clark Coe, M.D., Secretary of the Society. Philadelphia: William J. Dornan. 1890.

The volumes of annual transactions of all societies do not differ greatly from year to year, and we give sufficient praise in saying that this one is fully up to the standard of its predecessors. The annual sessions were held at Buffalo in September last, and were attended by twenty-one Fellows out of a total active membership of about seventy, about the usual proportion at such gatherings. The volume contains twenty-one papers on scientific topics, besides the annual address of the retiring President, Dr. John P. Reynolds, and a memorial of the late Dr. W. H. Byford of Chicago. No startling discoveries in gynecology have been made during the past year, and we therefore expect and indeed find the topics of the papers to suggest the every-day experiences of clinical practice. Drs. Skene, Hanks, Coe, Jewett, Murray, and Grandin, represent this end of New York State among the authors. The President's address is an admirable discussion of the ethical and sociological features of the marriage problem.

New York Charities Directory. Fourth Edition. 12mo, pp. 400. Published by the Charity Organization Society of New York City. 1890.

This is a classified and descriptive directory of the charitable and beneficent societies and institutions of the city of New York. It is as complete as it is possible to make a volume of this kind. We have given it a somewhat careful examination and have not thus far discovered the slightest omission or inaccuracy in it. An index with nearly three thousand headings facilitates its use. Maps are given showing the Society's division of the city into working districts. We cannot too highly commend this volume to the physician and to all who are charitably disposed. The former will find in it answers to all the perplexing questions constantly put to him by patients and their friends. To the latter it will serve as a judicious adviser, telling them where and how their benevolence may be best bestowed. We think it will surprise even many old residents of New York to read over the long lists of charitable organizations, which, according to the index, include everything from "beef-tea" to "moral aid."

Memorial Sketches of Dr. Moses Gunn. By His Wife, with Extracts from His Letters and Eulogistic Tributes from His Colleagues and Friends. Illustrated. Pp. 380. Chicago: W. T. Keener, 96 Washington Street.

This handsome work is the tribute of a true, loving wife to a noble husband, and it contains inspiration and encouragement for every reader. Moses Gunn, LL.D., M.D., was a famous surgeon and teacher of the faculty of Rush Medical College, Chicago. He died November 4, 1887. His experience in hospitals, on the field of battle, and in Europe are of absorbing interest.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, January 26, 1891.

ORLANDO B. DOUGLAS, M.D., PRESIDENT, IN THE CHAIR.

The Caustic Treatment of Cancer.—DR. DANIEL LEWIS read a paper on this subject. Cancer, he said, must be destroyed, and in some way removed from the body. Two methods had been employed: 1. By absorption, under which the tumor was supposed to be softened by some agent, as electricity, and changed into a form in which it could be carried away. This method, he thought, was so irrational and hazardous that it should be dismissed from consideration. If necessary, he could cite many cases in which the mild galvanic current had disseminated the disease. 2. By removal, accomplished by operation or escharotics. There were some surgeons who approved of nothing but the knife; some quacks claimed to be able to cure all cases better without the knife. Both parties were in error. The object of the paper was to point out the cases suitable for caustic treatment, and his views, he said, were based on the treatment of one hundred cases in hospital and private practice. Mild caustics were to be strongly condemned. Among them he named nitrate of silver, carbolic acid, resorcin, etc. These were not true escharotics, but rather irritants. An agent should be used which caused complete and rapid destruction of the diseased tissue, otherwise the absorbents would be stimulated to disseminate the disease.

For convenience he divided the cases of cancer into, 1, those of the breast, axillary and cervical glands, vulva, testes, penis, and rectum; 2, cancer of the cervical portion of the uterus, tongue, and tonsil; 3, cutaneous cancer, including cancer of the lip and external ear. The author then gave his reasons for preferring the knife in all these forms except the last, cases of cutaneous cancer. Regarding the treatment of cancer of the cervix uteri by caustics, he said that a considerable number of cases had been under his care, and all patients so treated excepting one were dead, and this patient could not live long. But, with regard to cutaneous cancer, or epithelioma, he saw no reason why ninety per cent. of the cases should not be cured if taken early. The most satisfactory method was by escharotics. The patients were usually beyond middle age, bore ether badly, dreaded the knife, and, if it were suggested, would postpone the operation. The resulting cicatrix from escharotics, when they were not left on too long, was usually smooth and white; recurrence was not more frequent than after the knife. The caustic was applied as a paste, of which there were three kinds most in use, namely, Jenning's, Marsden's, and Bougard's. The latter was preferable in some ways. The cutaneous surface was first broken by caustic potash, so that the paste would more quickly take hold. The paste should be reapplied until all diseased tissue had been eaten away. One application usually remained on twelve to twenty-four hours.

Bougard's paste is composed of: Wheat flour, 60 parts; arsenic, 1; cinnebar, 5; sal ammoniac, 5; corrosive sublimate, 50; solution of chloride of zinc, at 52°, 245 parts. Mix. Jenning's: Cocaine, 20 grains; caustic potash, 120 grains; vaseline, 60 grains. Marsden's: arsenious acid, two parts; mucilage of acacia, one part; form a paste which will not run.

Two men were presented who had had epithelioma of the lip removed by the escharotic, leaving scarcely a perceptible cicatrix.

The paper was discussed by Drs. C. W. Allen, G. H. Fox, and F. A. Burrall, who concurred in its principal features.

Results Obtained by the Use of Heat and Cold Applied to the Spine.—DR. B. D. KINNEAR, the author of the paper, said that while it was not his object to explain Chapman's system, yet he wished to draw attention to it, with the hope that the profession might study and use it, as he had himself been very successful in its employment. The system recognized five sets of nerves: those of sensation, of motion, of the glandular and secretory organs, those supplying the blood-vessels, causing them when active to contract, and nerves distributed to the ultimate cells of every bodily tissue. In applying this system to therapeutics, it was claimed than an excess of circulation in the central cell or cells of a nerve gave rise to abnormal action. In the case of nerves of sensation, for instance, according to the varying amount of blood supply to the centre would there be a feeling of itching, soreness, or neuralgia, indicating different strengths of nerve-current. The same illustration would apply to other nerves, according to their function. Equalized metabolic changes throughout the body were believed to constitute health, while unequal or irregular metabolic changes constituted disease; an equable circulation of the blood indicated health; an irregular circulation was disease. Dr. Chapman, he said, believed that nerve-force was due to circulation of blood within the nerve-centre. When there was hyperæmia within the centre, there was a powerful nerve-current; in anæmia it was weak. It was also Dr. Chapman's view that the circulation was balanced between the sympathetic and the atrophic nerves, the latter being those distributed to the ultimate tissue cells, which were thought to be cerebro-spinal.

Coming to actual application of treatment based on these views, heat or cold was applied to the different portions of the cord according to the indications for the one or the other. Rubber bags were made use of, containing two columns of hot or cold water or ice, so that they could be applied on both sides of the spine, for the purpose of influencing the sympathetic nerves lying deeply in these regions. By applying heat over the cervico-dorsal region, the sympathetic, controlling the circulation in the head, would be caused to contract, diminishing the blood supply and relieving, for instance, certain forms of headache, and other conditions dependent upon congestion. The warmth should not be greater than 115° F. to 120° F., otherwise it would have the contrary effect. In this way he said he had relieved in one case insensibility, or the comatose state of Bright's disease, as it came on from time to time. In another case of attacks of unconsciousness, throbbing temples, etc., heat was applied in the cervico dorsal region and cold over the dorso-lumbar region, the latter causing the blood to flow to the lower extremities. The method acted promptly in epistaxis, especially if acute; also in one or two cases of pneumonia, a case of milk-leg, swelling of the mammæ, threatened abortion, whooping-cough, hay fever, contractile paralyses, etc. An agent of such power, if applied carelessly, might do harm; for it was evident that to throw a quart of blood shortly upon a structure where it should not be, might produce congestion and inflammation.

Time did not permit of discussion of this and the next paper.
